LECTURES

ON

MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

BY JON. PEREIRA, ESQ., F.L.S.

LECTURE XXVII.

IN the last lecture I commenced the examination of WATER as a therapeutical agent, and I have now to continue the subject.

BATHS.

Let us, in the first place, notice the effects produced by, and the benefit to be obtained from, immersing one* or more parts of the body in liquid water, or aqueous vapour.

History.—The practice of bathing is of great antiquity, and, in fact, precedes the date of our earliest records. It was, and is employed, sometimes for the purpose of cleanliness, sometimes for the preservation of health, and frequently as a means of sensual gratification. Ablutions were practised by the ancient Hebrews, as you will find mentioned in the Old Testament. Baths were used by the Egyptians, as well as by the Hindoos, the Syrians, the Medes, the Persians, and other inhabitants of the East. The most ancient of the Greek writers also frequently mention them: thus Homer speaks of them in the Iliad and Odyssey. In the writings attributed to Hippocrates, you will find baths alluded to, and their effects noticed. Celsus describes the different parts of the baths, and the mode of employing them; but the best description will be found in the works of Galen. In 1752, Dr. Glasse, of Exeter, published "*An Account of the Ancient Baths,*" to which I must refer you for further historical information; or to the article "*Balneum,*" in Dr. Parr's Medical Dictionary, the historical account of which is taken almost verbatim from Dr. Glasse's memoir.

Effects and uses of baths.—The effects of baths depend, for the most part, on the temperature of the fluid employed, on its conducting power, and, in part also, on its pressure. We may, therefore, conveniently arrange them thus:—

(*a.*) LIQUID BATHS.

(1.) *The cold bath.*
(2.) *The cool bath.*
(3.) *The tepid bath.*
(4.) *The warm bath.*
(5.) *The hot bath.*

(*b.*) VAPOROUS BATHS.

(*b.*) *The vapour bath.*

Writers are not agreed on the precise temperature of the above baths, but the order in which I have arranged them, according to their respective degrees of heat, is that which is generally admitted.

(1.) *The Cold Bath.*—The temperature of this ranges from 33° F. to about 65° F.: when it is below 50°, it is sometimes termed a *very cold bath.* The *effects* of immersion in the cold bath are analogous to those already described as being produced by the application of ice or snow to the body, and, therefore, may be conveniently subdivided into primary and secondary.

(*a.*) *Primary effects.*—The sudden abstraction of heat from the surface, and the pressure of the water, produce a powerful shock on the system: a sensation of cold, (speedily followed by a sensation of warmth) contraction of the cutaneous vessels, paleness of the skin, diminution of perspiration, and reduction of the volume of the body, are the immediate effects. Shivering, and, as the water rises to the chest, a kind of convulsive sobbing, are also experienced. Continued immersion renders the pulse small,

and ultimately imperceptible—the respiration difficult and irregular: a feeling of inactivity succeeds—the joints become rigid and inflexible—pain in the head, drowsiness, and cramps, are experienced—the temperature of the body falls rapidly, and faintness, followed by death, comes on. Many of these symptoms are readily comprehended: the contracted state of the superficial vessels produced by the cold, together with the pressure of the water, causes the blood to accumulate in the internal vessels. The heart makes great efforts to get rid of this increased quantity of blood, and hence palpitations occur; but as the arteries remain contracted, the pulse continues small. The internal veins, therefore, being gorged with blood, the brain must necessarily suffer:—hence the headache, the drowsiness, and the cramps; and we should not be surprised if even apoplexy were induced. The difficult respiration depends on the accumulation of blood in the lungs. The contracted state of the superficial vessels accounts for the diminished perspiration; while the increased secretion of urine is referable to the blood being driven towards the internal organs.

(*b.*) *Secondary effects.* — In general, the immersion being only temporary, reaction quickly takes place; a sensation of warmth soon returns; the cutaneous circulation is speedily re-established; a glow is felt; perspiration comes on; the pulse becomes full and frequent; and the body feels invigorated. In weakly and debilitated subjects, however, this stage of reaction may not occur, or at least may be imperfectly effected; and usually, in such cases, the cold bath will be found to act injuriously.

The *uses* of the cold bath may be in part comprehended from the effects just detailed. It is evident that it ought not to be employed unless there be a sufficient degree of tone and vigour in the system to cause a perfect state of reaction; and, therefore, in weak subjects, its use is to be prohibited. So also in visceral inflammation, more especially peripneumonia, it is a dangerous remedy; since the determination of blood to the internal organs is increased by the cold, and it seems even within the range of probability that death might be the result. Apoplectic subjects who are unaccustomed to cold bathing, had also, for a similar reason, better avoid trying it. In some affections of the nervous system it has been found highly useful; for example, in tetanus and insanity. So also in any cases where we wish to increase the tone and vigour of the body, and where the before-mentioned objections do not exist, the cold bath may be used advantageously. It is a common opinion that immersion in cold water is dangerous when the body is heated by exercise, or other exertion; and hence it is customary with bathers to wait until they become cool. Dr. Currie has strongly combated both the opinion and the practice: the first, he says, is erroneous, the second injurious.

(2.) *The Cool Bath* (whose temperature is from 65° to about 85°) is analogous in its operation to the cold bath, but less powerful. It is commonly employed for the purposes of pleasure and cleanliness; but it may be resorted to, therapeutically, in the same diseases as the cold bath, where we are in doubt as to the power of the patient's constitution to establish full reaction. It is frequently used as a preparatory measure to the cold bath.

(3.) *The Tepid Bath* gives rise to a sensation of either heat or cold, according to the temperature of the body at the time of immersion. The temperature of this bath ranges between 85° and 95°. It cleanses the skin, promotes perspiration, and is used as preparatory to either of the before-mentioned baths. It is said to allay thirst, and it has been supposed that the water becomes absorbed. Where there is a tendency to apoplexy, it has been recommended to immerse the body in the tepid bath, and at the same time to pour cold water over the head.

(4.) *The Warm Bath* varies in its *effects* on different individuals. Its temperature is about that of the body, or a little below it: we may say from 95° to 98°. In general it causes a sensation of warmth, which is more obvious when the body has been previously cooled. The pulse is rendered fuller and more frequent, the respiration is accelerated, and the perspiration augmented. It gives rise to languor, loss of muscular power, faintness, and disposition to sleep. The *uses* of it are various. Sometimes to cause relaxation of the muscular system; as in dislocation of the larger joints: and also in hernia, to assist the operation of the taxis. In the passage of calculi, either urinary or biliary, it is employed with the greatest advantage: it relaxes the ducts, and thereby facilitates the passage of the foreign body. As a powerful antiphlogistic, it is employed in inflammation of the stomach, bowels, kidneys, bladder, &c. With the view of increasing the cutaneous circulation, it is used in the exanthemata, when the eruption has receded,—and to promote perspiration, in chronic rheumatism, and various chronic skin diseases.

(5.) *The Hot Bath* (the temperature of which is somewhat above that of the body) gives rise to a sensation of heat, renders the pulse fuller and stronger, accelerates the respiration, occasions intense redness of the skin, and copious perspiration,—causes

the vessels of the head to throb violently—brings on a sensation of fulness about the head, with a feeling of suffocation and anxiety,—and, if the immersion be continued, apoplexy may even be induced. Being a powerful excitant, this remedy must be used very cautiously. Paralysis, rheumatism, and some chronic diseases, are the principal cases in which it is employed.

(*b*.) *Vapour bath*.—The vapour bath differs somewhat from the warm or hot bath in its effects; the hot air and vesicular water to which the body is exposed in the vapour bath, being much worse conductors of heat than water in its usual liquid form: the temperature of the bath is neither so quickly, nor so powerfully felt, so that the body can support a higher heat, and for a longer period; and in addition, the pressure is less. Like the common hot bath, it acts as a stimulant to the skin, exciting the cutaneous circulation, softening and relaxing the cutaneous tissue, producing copious perspiration, accelerating the pulse, quickening the respiration, and inducing a feeling of languor, and a tendency to sleep. There are two modes of employing it—either by immersing the whole body in the vapour, which is, consequently, inhaled, or inclosing the body in a chest or box, so that the head is not exposed to the vapour, which, therefore, is not inspired. The aqueous vapour is conveyed into the chamber or box by a pipe communicating with a steam boiler. Sometimes it is made to pass through various vegetable substances, with the odour of which it becomes impregnated, and from which it is supposed, by some, to gain an increase or modification of therapeutical power. These are the *medicated vapour baths*. Sometimes the common vapour bath is accompanied by a process of friction, kneading and extension of the muscles, tendons, and ligaments, constituting the *massing* of the Egyptians, or the *shampooing* of the Indians. Here is the account of the process, as given by Dr. Gibney. "After exposure to the bath, while the body is yet warm from the effects of the vapour, the shampooman proceeds according to the circumstances of the case, from gentle friction gradually increased to pressure, along the fleshy and tendinous parts of the limb; he kneads and grasps the muscle repeatedly, presses with the points of his fingers along its course, and then follows friction, in a greater or less degree, alternating one with the other, while the hand is smeared with a medicated oil, in the specific influence of which the operator has considerable confidence. This process is continued for a shorter or longer space of time, and, according to circumstances, is either succeeded or preceded by an extension of the capsular ligament of each joint, from the larger to the smaller, causing each to crack, so as to be distinctly heard, which also succeeds from the process being extended to each connecting ligament of the vertebræ of the back and loins. The sensation at the moment is far from agreeable, but is succeeded by effects not dissimilar to what arise from brisk electrical sparks, taken from the joints in quick succession."

The vapour bath is applicable to a great variety of cases, a few only of which can I afford myself time to notice. You will, however, very readily comprehend those likely to be relieved by such a powerful stimulant. Whenever you wish to excite the vascular system, more especially the cutaneous portion of it, this remedy may be resorted to with advantage. The cold stage of an intermittent and malignant cholera are cases which readily suggest the employment of this agent. In rheumatism and gout, in old paralytic cases unaccompanied with signs of vascular excitement about the head, in various atonic affections of the uterine system, such as chlorosis, and some forms of amenorrhœa, in dropsy of old debilitated subjects, in various skin diseases, (in which class of complaints, I would particularly recommend Dr. Green's work, for an account of the good effects of the vapour bath), in scrofula, in chronic liver complaints of long standing, &c., you may employ this remedy frequently with advantage.

I ought not to leave this subject without alluding to the extensive use made of vapour baths in some parts of the world, particularly Russia, where we are told it is customary for the bathers to issue from the bathing houses while quite hot, and to roll themselves naked in the snow, and then return to the bath, not only without any hurtful, but apparently with beneficial, effects.

Local baths.—Baths are divided into general and local, according as they are applied to the whole body, or only to parts of it. Local or partial baths receive different appellations, according to the part of the body immersed in them. Thus we have the *semicupium*, or half bath, in which the lower extremities and hips are immersed; the *coxæluvium*, or hip bath, which receives the hips only; the *capitiluvium*, or head bath; the *pediluvium*, or foot bath; and the *manuluvium*, or hand bath. Their effects vary with their temperature, and are of the same kind as those already described as produced by general baths, but more localized. Sometimes we use them as revulsives; as the warm pediluvium in cerebral affections: sometimes as local agents: thus we frequently use the hip bath in uterine affections.

AFFUSION.

I proceed now to notice another mode of employing water externally, namely, by *affusion*, that is, the pouring of water over some portion of the body. It is the καταχυσις of Hippocrates.

History.—This practice is of very ancient date: as a hygienic agent and luxury it was practised by the Greeks and Orientalists at a very early period, and allusions to it will be found in the Odyssey of Homer. Hot, tepid, and cold affusions, are mentioned by Celsus, in the fourth chapter of the first book, and are recommended in some affections of the head. This last writer also states, that Cleophantus (a physician who lived about 300 years before Christ) employed the affusion of hot water in intermittents. For the best account of the effects and uses of cold affusion, I must refer you to the "Medical Reports" of Dr. Currie. In the tenth volume of the MEDICAL GAZETTE you will also find a paper on the affusion of cold water on the head, by Dr. Copland, which well deserves your perusal.

Mode of applying affusion.—In many cases, the object is to use the affusion to the *head* merely. If the patient be able to sit up, let him incline his head over a large vessel, say a pan or tub, and then pour the water from a height of two or three feet from an ewer or large pitcher. If, however, he be too ill to be removed, he must incline his head over the side of the bed. In children, it will be sufficient to squeeze a large sponge at some height above the head, as recommended by Dr. Copland. In some cases it is necessary to guard against the cold water coming in contact with the chest.

When the object is to apply the affusion to the *whole body*, the patient must be placed in a large tub or pan—for example, a bathing-tub or washing-pan—and then an attendant standing on a chair may readily effect it. The time that the affusion should be continued will vary according to circumstances; I should say from $\frac{1}{4}$ to 2 or 3 minutes; but in some cases it has been employed for 20 minutes. After the affusion, the body should be carefully wiped dry, the patient wrapped up warm, and placed in bed.

Effects.—The effects of affusion depend partly on the temperature of the water, and partly also on the sudden and violent shock given to the system by the mechanical impulse of the water; hence the reason why the effects vary according to the height from which the liquid is poured.

1. *Of the affusion of cold water*—that is, of water whose temperature is between 32° F. and 65°.—To a certain extent the effect of this agent is analogous to that of the cold bath, but modified by two circumstances, namely, the short period during which the cold is applied, and the mechanical influence of the stream: hence, its primary effects are very transient, and reaction follows very speedily. By a long continuance of affusion, however, the heat of the body is very considerably reduced, and the same diminution of vital action occurs as when the cold bath is employed. The sensation of cold, the constriction of the skin, and the contraction of the superficial vessels, first experienced in the part to which the water is applied, is very speedily communicated to the rest of the system by sympathy, in consequence of the shock received; the effects of which are perceived in the nervous, vascular, secreting, and cutaneous systems. The temperature of the whole body falls, the pulse becomes reduced in volume and frequency, the respiration is irregular, and convulsive shiverings take place, faintness, and, in fact, all the effects already described of the cold bath are produced. During this condition the excretions are suspended. "When," says Dr. Copland, "the stream of water is considerable, and falls from some height upon the head, the effect on the nervous system is often very remarkable, and approaches more nearly than any other phenomenon with which I am acquainted to electro motive or galvanic agency."

After the affusion, re-action is soon set up, the heat of the body is re-established, the pulse becomes full and regular, though sometimes reduced in frequency, the thirst is diminished, and frequently perspiration and tendency to sleep are observed.

Cold affusion is used principally in those cases where it is considered desirable to make a powerful and sudden impression on the system: for as a mere cooling agent, it is inferior to some other modes of applying water. Thus it is employed, for the most part, in fevers, and affections of the nervous system. It is objectionable in visceral inflammation, on account of the determination of blood which it produces to the internal parts. Cold affusion has been employed with great benefit in *fevers*, both continued and intermittent. It may be used with safety, according to Dr. Currie and others, "when there is no sense of chilliness present, when the heat of the surface is steadily above what is natural, and when there is no general or profuse perspiration." It is inadmissible during either the cold or the sweating stage of fever, as also in the hot stage, when the heat is not greater than ordinary. In some instances it seems to act by the shock it communicates to the system; for the effect is almost immediate, the disease being at once cut short. The

patient has fallen asleep immediately afterwards, profuse perspiration has succeeded, and from that time recovery begun to take place. This plan of extinguishing a fever, however, frequently fails; and in that event the patient may be in a worse condition; hence the practice is not often adopted. I think the cases best adapted for the use of cold affusion are those in which there is great cerebral disorder,—either violent delirium or a soporose condition. My friend, Dr. Clutterbuck, in his work on Fever, says he has seen pulmonic inflammation and rheumatism brought on by cold affusion in typhus; but he adds, "I have not, in general, observed that the situation of the patient was rendered materially worse by the combination."

In the *exanthemata*, cold affusion has been employed in the fever which precedes the eruption, as also after this has been established; it has been used in scarlet fever, and also in small-pox; likewise in measles; but I would strongly advise you, however, not to employ it in the latter disease, on account of the tendency to pulmonary inflammation, in which cold affusion is prejudicial.

Croup is another disease in which cold affusion has been used with advantage, principally with the view of removing the spasm of the glottis, which endangers the life of the patient.

In *inflammatory affections of the brain*, especially of children, after proper evacuations have been made, it is useful. In many cases of *narcotic poisoning*, cold affusion is of the greatest service. I have already alluded to its employment in poisoning with hydrocyanic acid, and in asphyxia caused by the inhalation of carbonic acid; so also in poisoning with opium, belladonna, and other narcotic substances,—in intoxication,—in asphyxia from the inhalation of sulphuretted hydrogen gas, or of the vapours of burning charcoal,—this practice is most advantageous; and I shall on future occasions find it requisite to draw your attention again to its application. In *hysteria* and *epilepsy* it is oftentimes serviceable: it diminishes the duration of the paroxysms, and relieves the comatose symptoms. In *puerperal convulsions*, Dr. Copland relies on cold affusion and blood-letting. In *mania* it is oftentimes serviceable; as also in *tetanus*.

2. *Cool affusion* has been employed instead of the cold; and in weak irritable subjects it is always preferable. Dr. Currie regards it as a milder form of the cold affusion, as a preparatory means to which it is sometimes used. It has been used in febrile diseases and paralysis.

3. *Of tepid affusion.*—The affusion of tepid water is frequently resorted to as a substitute for that of cold water, where great dread is entertained of the latter agent, or where there is doubt as to the production of a perfect reaction after the application of cold water, or where there is some pulmonary disease. It may be regarded as a safer, though less powerful means. Thus it is very useful in febrile complaints, especially of children. It is very beneficial in scarlet fever, as I have seen on several occasions. Dr. Currie thinks that it reduces the temperature more than cold affusion; first, because the evaporation is greater; secondly, because it does not excite that reaction by which heat is evolved. It diminishes the frequency of the pulse and of respiration, and causes a tendency to sleep. He states that he has not found its effects so permanent as those of the cold affusion; and that he never saw it followed by the total cessation of regular fever. In other words, it produces a much less powerful shock to the system, and, therefore, is less influential over disease. In hectic fever, however, the paroxysm is sometimes completely extinguished by the affusion of tepid water at the commencement of the hot stage.

4. *Warm affusion* excites very pleasant sensations, but which are soon followed by chilliness, and oftentimes by pulmonary affections. It has been used in mania with advantage: it reduces the frequency of the pulse and of respiration, and occasions a tendency to repose; but the effects are much more temporary than those produced by the warm bath.

Washing or Sponging.

Cold, cool, or tepid washing or sponging the body, may be used in febrile diseases, with great advantage, in many cases where affusion is not admissible, or where timidity on the part of the patient or practitioner prevents the employment of the latter. Dr. Currie remarks, that in all cases of fever where the burning heat of the palms of the hands and soles of the feet is present, this method of cooling them should be resorted to. A little vinegar is frequently mixed with the water, to make the effect more refreshing. Washing or sponging must be effected under precisely the same regulations as those already laid down for affusion.

Shower Bath.

The shower bath is similar in its effects to affusion, but milder in its operation, and is mostly employed in chronic diseases, or as a hygienic agent. In various affections of the nervous system, more especially insanity, it is very useful. In many cases it is a valuable agent when we are afraid to venture on the common cold

bath or cold affusion, since it is less likely to cause cramps or other symptoms indicative of a disordered state of the nervous system.

THE DOUCHE, OR PUMPING.

Definition.—The French word *douche*, or the Italian *doccia*, signifies a continued current of fluid applied to, or made to fall on, some part of the body. Dr. Parr states that it is synonymous with our word "*pumping*," and with the Latin word *stillicidium*. At Bath, for example, the waters are applied, say to a paralyzed part, by means of a pump, and the degree or quantity of the application is determined by the number of times the handle is raised or depressed. The water, however, does not issue in gushes, but in a continuous stream. This is evidently what the French would call a *douche*, but I do not think that our word "pumping" is applicable to what they term a "*douche de vapeur*."

History.—It is uncertain at how early a period this remedy was in use. The following passage from Cælius Aurelianus has been supposed by some to refer to this mode of employing water. "Item *aquarum ruinis* partes in passione constitutæ sunt subjiciendæ, quas Græci κατακλυσμοὺς appellant, plurimum etenim earum *percussiones* corporum faciunt mutationem." By some, however, this passage is supposed to refer to affusion.

General operation.—The effects of the douche depend on several circumstances, such as the nature of the fluid employed, whether vapour or liquid, and if liquid, whether simple or some saline water: the temperature also must have an influence, as is very evident,—the size and direction of the jet, the force with which it is applied, and its duration. At Bath, Dr. Falconer tells us, "from 50 to 200 strokes of the pump is the number generally directed to be taken at one time, which, however, may be increased or diminished according to the age, sex, strength, or other circumstances of the patient." On the Continent, it is rarely employed for a longer period than 15 or 20 minutes.

(*a.*) *The vapour douche* is nothing more than a jet of aqueous vapour directed on some part of the body, its action depending principally on the temperature of the fluid, since its mechanical effects are comparatively slight.

Sometimes *steam* has been used—that is, aqueous vapour heated to 212° F.; and, of course, it acts as a caustic if sufficiently long applied, causing sometimes an extensive and deep eschar. In this respect its action is similar to that of boiling water, from which, indeed, it principally differs in the circumstance of having a much larger quantity of specific heat, and in the great facility with which we can localize its effects. It may be readily applied to any part of the body by means of a small boiler (copper or tin), furnished with a pipe and stop-cock, and heated by a spirit lamp. It has been used as a powerful counter-irritant in diseases of the hip joint, neuralgic pains, chronic rheumatism, &c.; but the objections to its use are the great pain and the danger of its employment; for it is a more painful application than many other modes of causing counter-irritation, while its effects are inconstant. In the *common vapour douche* the temperature of the aqueous vapour does not exceed that employed in the vapour baths already described; and in such cases it may be regarded as a kind of local vapour bath. Thus in some affections of the ear, as otitis, otorrhœa, and otalgia, a stream of aqueous vapour may be applied to the meatus auditorius externus with great benefit; and the most ready means of effecting this is by a funnel inverted over a vessel of hot water, the ear being placed over the orifice of the funnel.

(*b.*) *The liquid douche.*—The action of this depends in a great measure on the temperature of the liquid, but in part also on the mechanical effect produced by the striking of a column of water against a living part. This effect of percussion is common to both the cold and hot douche, and by continuance excites pain and inflammation of the part. This local excitement is observed almost immediately when hot water is employed, but takes place more slowly when we use cold water; indeed, the long action of a stream of cold water may act as a sedative, and cause all the effects which I have already described as the primary effects of cold applications.

The effect of the douche, is, however, not altogether local, since the neighbouring parts, and even the whole animal economy, soon become affected. A column of water twelve feet high, made to fall perpendicularly on the top of the head, excites such a painful sensation, that, we are told, the most furious maniacs who have once tried it may sometimes be awed merely by the threat of its application; and hence one of its uses in madness, as a means of controlling the unfortunate patient.

The *cold douche* is applicable to those cases of local disease requiring a powerful stimulus. For example, chronic affections of the joints, of long standing, whether rheumatic, gouty, or otherwise, paralytic affections of the limbs, old glandular swellings, and those forms of insanity in which there are no marks of determination of blood to the head. The

warm douche may be employed in similar cases.

For a variety of local purposes, a syringe is employed to throw a jet of water on particular parts, as into sinuous ulcers, or into the vagina, into the ear, into the rectum, &c., constituting thus a kind of douche.

BOILING WATER, AQUEOUS LOTIONS, FOMENTATIONS, POULTICES.

Boiling water is never employed for internal purposes, but externally it has been used as a powerful irritant and a speedy vesicant; its action being in this respect analogous to steam, already noticed, and objectionable on the same ground, namely, the great pain, and the uncertainty of its effects; in addition to which may be mentioned, the difficulty of localizing its action. When applied in diseases of internal organs, it may be regarded as a powerful counter-irritant. In the application of medicines to the common integuments, by what is called the *endermic* or *emplastro-endermic* methods, the cuticle or epidermis must be in the first place removed; and one of the most speedy ways of raising it is by the application of boiling water; but I think a metallic plate, heated by immersion in boiling water, a much better method of producing the effect.

Hot, *warm*, and *cold* water, applied to particular parts of the body, may be regarded as local baths. I ought, however, to notice, that cold water is applied to the skin in order to produce evaporation, and thereby to generate cold, with the view of relieving local irritation and inflammation. In ophthalmia, phrenitis, and even in gout (though in the latter complaint the practice has been objected to), cold water lotions are employed with great advantage. One method of treating burns is by the application of cold water, and, if I am to judge by my own sensations, it is by far the most agreeable. By some, however, warm water is employed as an emollient application in burns and scalds, and knowing that my friend Mr. Luke, one of the surgeons to the London Hospital, has long employed it in these cases, I requested him to state to me the result of his observations on its use. The report which he was kind enough to furnish me with is as follows:—

" After several years' experience in the use of warm water as an application in the first treatment of scalds and burns admitted into the London Hospital, I am enabled to say, that the general result has been very satisfactory. It has almost in every instance appeared to sooth and mitigate pain, and, in many instances, to facilitate the recovery of the patient from the great constitutional depression so frequently attendant upon cases of severity. In these respects I think it exceeds in value all other means which I have seen used. It also appears to me to have exerted a very beneficial influence in mitigating the consecutive inflammation, rendering the after consequences less severe locally, and the reparative process more speedy, than under other modes of treatment. The most striking exemplifications of its value have been seen in the treatment of the scalds and burns of young children; and of those cases where the vitality of the skin has not been completely destroyed. The water has generally been used in the form of fomentations, repeatedly changing the flannels, and taking care that the surface of the skin was exposed as little as possible. The occasional use of poultices has also been adopted, and with much benefit; although their weight, when large, has rendered them not so convenient as fomentations; they obviate, however, the evil arising from the frequent renewal of the latter, and the consequent mechanical irritation. Inability to continue the warm bath for the requisite length of time has been the reason for its not being used in these cases."

Warm fomentations and poultices (made of bread or linseed meal) may be regarded, in reference to their effects, as a kind of local bath.

INTERNAL USE OF WATER.

1. *Taken into the stomach.*—*Cold water* was employed as a drink in *fevers* in the time of Hippocrates, who, as well as Celsus, Galen, and others of the ancients, strongly recommended its use. Celsus, in speaking of ardent fever, says, " cum vero in summo incremento morbus est, utique non ante quartum diem, magna sit antecedente, frigida aqua copiose præstanda est, ut bibat etiam ultra satietatem."

Cold water constitutes the *febrifugum magnum* of Dr. Hancock. We are indebted to Dr. Currie for examining the circumstances under which its exhibition is proper. According to him, it is inadmissible during the cold or sweating stage of fever, but may be employed with safety and advantage when the skin is dry and burning. In other words, the regulations for its administration are precisely the same as for the cold affusion. When exhibited under proper circumstances, it acts as a real refrigerant, reducing preternatural heat, lowering the pulse, and disposing to sweating. I ought, however, not to omit noticing, that serious and even fatal consequences have resulted from the employment of large quantities of cold water by persons who have been rendered very warm by exercise and fatigue. Besides fever,

there are many other affections in which cold water is a useful remedy. For example, to facilitate recovery from an attack of epilepsy or hysteria, and also in fainting, a draught of cold water is oftentimes beneficial. There are also various morbid states of the alimentary canal in which cold water may be administered with advantage; for example, to diminish irritable conditions of the stomach, and to allay vomiting and gastrodynia. Large quantities of cold water have sometimes caused the expulsion of intestinal worms (both the tænia and oxyuris vermicularis, or small thread worms, commonly termed ascarides, and which are found in the large intestines of children, particularly in the rectum). Salt water acts more efficaciously, as I shall hereafter have occasion to notice.

Tepid and *warm* drinks are employed for various purposes; as for promoting vomiting, to dilute the contents of the stomach, and render them less acrid, as in cases of irritant poisoning; but you will of course bear in mind, that in poisons, acting by absorption, diluents are objectionable, since they facilitate this process, and, therefore, ought not to be employed unless vomiting is taking place, or you have the stomach-pump at hand. Warm aqueous drinks are administered with the view of exciting diaphoresis, as in gout, rheumatism, catarrh, &c., and to promote their operation you had better keep the patient warm in bed, in order to determine to the surface. Warm liquids are oftentimes used as emollients; for example, to allay irritable and troublesome cough, particularly when this appears to depend on irritation at the top of the larynx.

2. *Injected into the rectum.*—Clysters of water, usually tepid, are employed to excite alvine evacuations. I have already mentioned my opinion, that the repeated introduction of several pints of liquid into the rectum is objectionable; since, by distention, the gut becomes less susceptible to the natural stimulus of the fæces. *Cold water* is thrown into the rectum sometimes to check hæmorrhage—to cause the expulsion of worms (the small thread-worm)—to allay pain—in poisoning with opium—in inflammation of the bowels, and in various other cases. *Warm water* is sometimes employed to promote the hæmorrhoidal flux, and thereby to relieve affections of distant organs; as an emollient, to diminish irritation either in the large intestine itself, or in some neighbouring organ, namely, the bladder, prostate gland, or uterus; to promote the catamenial discharge, &c.

3. *Injections into the vagina.* — Dr. A. T. Thomson speaks very favourably of the use of cold water applied in uterine hæmorrhages by means of the stomach-pump, and he says he has seen it employed in several cases most successfully. Warm water may be used to diminish irritation or pain in the womb,—to promote the lochial discharge, &c.

4. *Injections of water into the bladder* are sometimes employed; either to diminish irritation in this viscus, or to distend it previously to the operation of lithotrity.

5. *Injections into the urethra* have also been used to allay irritations, or to check discharges from the mucous lining.

6. The *inhalation of aqueous vapour* acts as a serviceable emollient in irritation or inflammation of the tonsils, or of the membrane lining the larynx, trachea, or bronchial tubes. It may be employed by means of Mudge's inhaler, or by merely breathing over warm water. Various narcotic and emollient substances are frequently added to the water, without increasing the therapeutical power. In some pulmonary complaints, Dr. Paris states he has been long in the habit of recommending persons confined in artificially warmed apartments to evaporate a certain portion of water, whenever the external air has become excessively dry by the prevalence of the north-east winds, which so frequently infest this island during the months of spring; and the most marked advantage has attended the practice.

7. The *injection of warm water* into the veins was proposed by Magendie as a remedy for hydrophobia, but it has neither theory nor experience to recommend it. However, in a disease which has hitherto resisted all known means of cure, practitioners are glad to try any remedy that may be proposed, however improbable or unlikely of success. I have already mentioned* a case in which I tried warm water injections, but without much benefit. Verniere has proposed to distend the venous system with warm water, to check or stop absorption in poisoning, by those agents whose operation depends on their absorption; for example, opium. I am not aware, however, that it has been tried on the human subject. Warm water is sometimes a medium for the introduction of other more powerful agents into the circulating system, as, for example, tartar emetic.

Medicamenta hydrolica.

The *pharmaciens* of Paris have for several years past adopted a new pharmaceutical nomenclature, originally proposed by M. Chereau; and I propose from time to time to offer you some specimens of it. On the present occasion I shall allude to those medicines which are called *hydroliques*; a term meant to include all those

* Medical Gazette, vol. xvii. p. 135.

preparations consisting of water charged with medicinal substances. When procured by solution or mixture, they are denominated *hydrolés;* but when distillation is employed, they are called *hydrolats*.

1. *Hydrolés.*—These are subdivided into mineral, vegetable, and animal. Of *mineral hydrolés*, or *hydrolés chimicobasiques*, I may mention, as examples, goulard water, the arsenical solution, lime water, the solution of iodide of potassium, &c. As instances of *vegetable hydrolés*, or the *hydrolés phytobasiques*, I may cite almond emulsion, vegetable infusions, and decoctions, mucilage, &c. The *animal hydrolés*, or *hydrolés zoobasiques*, are commonly termed broths.

2. *Hydrolats.* — These are the *distilled waters*, and are too well known to require further notice.

SOME FURTHER

REMARKS ON THE PROTECTIVE POWER OF VACCINATION.

To the Editor of the Medical Gazette.

SIR,

THE frequent failure of vaccination to continue its protective power (wholly or partially) after the lapse of several years, to those whom it secured from small-pox in early childhood, has made its friends alive to every suggestion for increasing its efficacy, and the confidence which, on the whole, it still continues to deserve from the public. On one or two of these suggestions I shall beg leave to make some remarks.

One is, that the virus of cow-pock is becoming, as it were *effete*, by its long and uninterrupted transmission through the human subject; that its effects are now almost exclusively confined to the production of local vesicles; and that it therefore becomes necessary to renew the parent stock by insertion of virus from the cow.

But as most of the practitioners who have been engaged, even for a long series of years, in vaccination, have never seen the disorder in the cow, it is of some importance that they should be aware what it is, and to what extent it affects the constitution. We cannot do better than to recur to the original report and experiments of the illustrious inventor of vaccination.

Dr. Jenner, in the first treatise, in the year 1798, which introduced the subject to public notice, entitled, "An Inquiry into the Causes and Effects of Variola Vaccina, a disease dicovered in some of the western counties of England, particularly Gloucestershire, and known by the name of the Cow-Pox," gives the following description of the disease, both in the cow and the human subject:—

"It appears on the nipples of the cows, in the form of irregular pustules. At their first appearance they are commonly of a palish blue, and are surrounded by an erysipelatous inflammation. . . . . . The animals become indisposed, and the secretion of milk is much lessened. Inflamed spots now begin to appear on the hands of the domestics employed in milking, which quickly run on to suppuration. . . . . . Absorption takes place, and tumors appear in each axilla. The system becomes affected; the pulse is quickened; and shiverings, with general lassitude and pains about the loins and limbs, with vomiting, come on. The head is painful, and the patient is now and then even affected with delirium. These symptoms, varying in their degree of violence, generally continue from one day to three or four, leaving ulcerated sores about the hands, which, from the sensibility of the parts, are very troublesome, and commonly heal slowly; frequently becoming phagedenic, like those from whence they sprung."

Dr. Jenner then states the well-known fact, that persons who have gone through cow-pox taken in this way, remained ever after unsusceptible of small-pox; and this he confirmed by inoculating with the latter disease, but without effect, persons who had gone through the disease from the cow at various periods of their life—from twenty to twenty-five years.

Let us now see what was the effect of transmitting the cow-pock virus from one human subject to another. The first patient ever vaccinated in this way was a healthy boy, eight years old; in whose arm Dr. J. inserted, by means of two superficial incisions, some matter taken from the sore of a dairy-maid who had been infected by her master's cows. The date of this original experiment is the 14th of May, 1796; nearly forty years ago.

Dr. Jenner's report of this case is the following:—"On the seventh day he complained of uneasiness in the axilla, and on the ninth he became a little chilly, lost his appetite, and had a slight

headache. During the whole of this day he was perceptibly indisposed, and spent the night with some degree of restlessness; but on the day following he was perfectly well." The appearance of the incisions in their progress to maturation, he states, resembled that of variolous matter, only that the fluid in this case was more limpid, the efflorescence more of an erysipelatous look, and the whole died away without giving the least trouble, leaving scabs and eschars on the inoculated part.

In the following year a child was inoculated with matter taken immediately from the cow. He became indisposed on the sixth day, vomited once, and felt the usual slight symptoms till the eighth day, when he appeared perfectly well. The inoculation of several children and adults from this source followed, most of whom were stated to have sickened on the sixth day, and were well on the seventh; but in three, a secondary indisposition arose, in consequence of inflammation on the arm, which, however, soon subsided. All these were afterwards tested with small-pox inoculation, and resisted its effects.

Three years afterwards, Dr. Jenner inoculated a considerable number of persons from virus obtained from Dr. Marshall, the source of which was an infected cow in a London milk farm; and all of them showed the same mildness, not only in comparison with small-pox, but also with the disease as produced in the milkers' hands, by casual infection. Dr. Jenner concludes by the following paragraph, so much to the point in question. "Whether the nature of the virus will undergo any change from being further removed from its original source, in passing successively from one person to another, time alone can determine. That which I am now employing has been in use nearly eight months; and not the least change is perceptible on its mode of action, either locally or constitutionally. There is, therefore, every reason to expect that its effects will remain unaltered, and that we shall not be under the necessity of seeking fresh supplies from the cow."—*Continuation of Facts, &c.*, 1800; p. 22.

Let it be granted that the experience of forty years has so far compelled us to modify the inference which Dr. Jenner drew from his first experiments as to shew that we cannot always depend on the test of very early exposure to small-pox after vacination, as a security for the remainder of life, this, at least, is certain, that the cow-pox, as soon as it was transferred to the human subject by artificial insertion, (and even in one or two cases by direct inoculation from the infected animal) was *immediately* brought down to a state hardly, if at all, different from that in which we daily see it; though it must now, on a fair computation, have passed through a thousand successive subjects, since each transmission occupies no more than a week in regularly sustained practice. We still can generally detect a slight sickening about the fifth or sixth day; more decidedly so in older children and adults than infants, but chiefly, I believe, owing to the inability of the latter to describe the symptoms, and from the frequent interference of other slight causes of derangement of the functions, especially during the long period of dentition, which makes it difficult to distinguish the sickening which is due to vaccination alone. That some constitutional effect is produced by vaccination is still shewn by the unanswerable test of re-vaccination during the early progress of the first vesicles, as proposed by Mr. Bryce, those of the later insertion being thereby hurried in their course, till they overtake the former, and the final areola round both being simultaneous.

What advantage, then, are we likely to obtain by recurring to the original source from the cow? Is it not most probable, that after one or two transmissions through the human subject, we should then obtain a virus, neither more nor less active than that which we are now using, unchanged by more than thirty years' incessant re-production?

I think it not at all unlikely that the casual disease, as it still appears in the hands of the milkers, does in fact afford a more perfect security from small-pox than that which follows common vaccination; though this is not borne out by the analogy of small-pox itself. It should be remembered, however, that cow-pox is not always the mild and easy disorder which follows the vaccine lancet; and if it does not endanger life in robust farm-servants, even in them it produces such a degree of indisposition and local suffering, as deserves calculation when young infants are to be the subjects. If less than this will not suffice for perfect security, what parent

would not shrink, what surgeon would not hesitate, to pass the hand of a delicate infant over the ulcerated teat of a diseased cow, even were it always at hand, to yield its virus in due activity? And this leads to another suggestion, on which I wish to make some remarks, namely, the propriety of infant vaccination.

One of your correspondents, Mr. Grantham, of Crayford *, suggests that the vaccine inoculation is not so likely to produce its full constitutional effect on suckling children, as on those of a more advanced age; and he gives a few examples to confirm this opinion. This leads him to propose, as a general rule, "that no child should be vaccinated during the period of lactation;" by which he means "the first nine months."

Every suggestion from a respectable source, and which claims to be founded on personal experience, demands attention; though I believe this opinion would not be found ultimately correct, if tried by the long and well-combined experience of a multitude of accurate observers, which alone could fairly establish so general an inference. Neither is it supported, that I am aware of, by any observed analogy.

I know of no reason why the constitution of infants, deriving their food from their mothers' breast, should on that account be less liable to undergo that inexplicable change during the first attack of this disease, which protects them from a second for the rest of life. Nor do I believe that the few other diseases of similar character afford any confirmation of this opinion.

But be this as it may, as security from small-pox is the great object of the parent, it is obvious that this delay of vaccination can only apply with propriety to those cases in which infants are brought up in remote and retired situations, and are not permitted to wander beyond the bounds of their nurseries or secluded grounds; and moreover, who possess that habitual good health which will enable them to contend with casual variolous contagion on fair terms, should it unfortunately stray within their reach. It was a most valuable discovery, that of disarming this dreaded disease of its worst terrors, in the greater number of instances, by inoculation; but every careful practitioner, before he thus introduced small-pox, thought it necessary to select his patients, and to prepare them by previous diet and medicine. A weak, sickly infant, or one hardly recovered from some trying disorder, was rejected by the inoculator, and was most scrupulously removed from the focus of infection. Compare this with infant vaccination, communicating nothing but by actual insertion, at all times safe, even a few hours from birth, when demanded by the presence of unavoidable variolous contagion; equally easy to be imparted, and correct in its progress at any age; and which seldom, if ever, need be refused to the most infirm and weakly child, except during the actual presence of some specific disease, or of a few forms of cutaneous eruption.

But it is chiefly in large populous towns that this opinion of the inexpediency of early vaccination would prove the source of infinitely more evil than that which it could ever be reckoned on preventing. The infant who is the sole object of care to one attendant, who occupies a spacious nursery, takes daily exercise within the privileged rails of a London square, and is (or is supposed to be) anxiously secluded from any intercourse with the crowds who fill the adjacent streets, may have a fair chance of escaping this dreaded contagion during all the first months of childhood; but who shall protect the child of the labourer,—of the industrious artizan,—of the petty shopkeeper,—of that large class who form the bulk of those who now derive benefit from the public establishments for gratuitous vaccination? All these are well and respectably housed when they occupy an entire floor of a fourth-rate tenement, their apartments opening into a landing six foot square, and reached by a narrow staircase common to all. Supposing a single case of small-pox to occur under a roof thus tenanted, who can calculate the risk of infection to an infant cradled in any part of it during the long period of, perhaps, three weeks of incessant danger, considering the degree of promiscuous intercourse which the common wants of all the inmates demand, and the utter neglect of any thing approaching to quarantine regulations in these crowded abodes? Nor is the out-door risk to the infant trifling, when small-pox is rife. The mother, if a small

* Med. Gaz. Feb. 20th.

shopkeeper, is constantly seen serving her customers with her child in her arms; it must either accompany her when out on her needful business, or is perhaps trusted to the care of a young girl, who loiters on her errands on paved steps or blind alleys, always thronged with children of all ages, among whom the convalescent from small-pox is glad to take refuge, from the crowd that encumbers the public streets.

On consulting my register of vaccination, I find, as I shall presently state, that rather more than two-thirds of the whole number that apply are infants not exceeding the age of nine months; and I think the proportion in private practice is not at all lower. Many mothers, indeed, delay weaning their infants till after vaccination, with the feeling (natural enough to mothers) that all their troubles, great or small, are better borne when they have the breast to pacify them. In short, I hardly know any opinion that would prove a greater obstacle to the diffusion of the blessings of vaccination, than that of its inexpediency during the first nine or ten months of infant life.

I shall conclude with a few particulars of what may be called the *statistics* of vaccination, derived from the experience of many years as surgeon to one of the stations of the National Vaccine Establishment. The station is in the centre of Bishopsgate parish, in the city of London. I may premise, that the majority of applicants are not among the very lowest class, nor can they with any justice be called *paupers;* but are, for the most part, I believe, of the class of journeymen, or *operatives*, in one line or another. I may also add, that I am often struck with the large proportion of fine healthy children amongst them, who shew in their dress and about their persons nothing of the foulness of skin, and ragged squalidness, that attend utter poverty and neglect.

Selecting nearly the last four thousand patients, in the order in which they stand in my register-book, as affording a sufficient number for a fair average, their ages are as follows:—

377	under three months.
2342	above three months, and not exceeding nine.
1281	above nine months.
4000	

It appears, therefore, that 2719 of the 4000, or 68 per cent. of all that apply, are not more than nine months old; and probably quite as many are children actually at the breast; for although some of these may be already weaned, a great many remain sucklings some months longer, from the obvious motive in the mothers to delay a further increase of family. Of the 1281 above nine months, a very few only were adults; and most of these were merely tested by inoculation, to ascertain the permanency of the protection produced by a previous operation.

I regret that though the numbers in my register are gradually mounting to several thousands, I can make no satisfactory approach to determining the proportion of failures to the successful cases. This arises from the neglect in patients to attend a second time—a neglect which we all have to complain of in our public stations. Out of the 4000 above mentioned, no less than 1409 never appeared after the first inoculation; and 69 more, out of about 160, in whom the operation was repeated. This must no doubt be partly attributed to the vaccination not taking at once, and the mothers, perhaps living at an inconvenient distance, and with difficulty persuaded to come at all, not being inclined to trouble themselves further about the matter. But on occasionally visiting them at their own houses on the eighth day, when pressed for a supply of virus, I have more commonly found what I was in search of; and then non-attendance has been owing to their taking for granted (as, in fact, they generally do, say what you will) that the disorder, when once in progress, will go on very well to the end, without further advice or inspection. A very prevailing prejudice, against opening the vesicle, also keeps away many. I can, therefore, only give the proportions as they stand, and with the above-mentioned limitation.

Deducting from the 4000 patients, 1478, who failed to attend after the first and second inoculation, and also 50, who were merely tested to ascertain their security after a former vaccination, there will remain 2742 first cases, who were seen again on the eighth day, and, when necessary, on the tenth or the eleventh, and in whom the result is as follows:—

2387	2315	satisfactory after first inoculation.
	72	satisfactory after second ditto.
85		entirely failed, or irregular from various causes.
2472		

These numbers would give one entire failure, and twenty-eight that succeed; but, for the reasons above mentioned, I cannot at all depend on the accuracy of the inference.

The reasons for repeating the vaccination (which was almost always done on the eighth day from the first) were, either that it had totally failed, or else, that out of eight punctures that I usually make (four in each arm) perhaps only one had taken, and this, though correct in appearance, was languid, small, and not well advanced. In twelve of these cases, the second insertion, when succeeding, shewed Bryce's test in a most unequivocal manner; a regular areola, simultaneous in both the earlier and later vesicles, coming on four or five days after the second operation. When the vesicles are not correct on the eighth day, I do not re-inoculate them; but recommend the patients to return after some months.

Some of the incorrect varieties are the following:

1. When the vesicles are prominent, very itchy, and the contained fluid yellow, and approaching to pustular. These soon become covered with an amber-coloured scab, which is constantly renewed by scratching; differing in this respect from the perfectly correct vesicle, which gives little, if any, local irritation, and therefore may be kept unbroken, except by accident, during its whole progress. In this itching vesicle the period of the areola is, however, distinctly marked, though, perhaps, this inflammation is somewhat hastened and much diffused. It is generally connected with some cutaneous irritation during dentition, and notably with the oozing of acrid humour from cracks behind the ears. It is not unlikely that, in most of these cases, where the areola is decided, the vaccination would be sufficient for security; but it is not safe to trust to it, without a further test at some more distant period.

2. When the vesicles are very pale, flat, containing scarcely any fluid, and that not quite limpid, but somewhat milky. If raised by the hand, they feel quite loose and flabby on the eighth day, instead of being already hard and red at the base. This state is not unfrequently produced by much purging, and therefore often appears at the end of summer, when children are thus affected. By attending to the bowels, these cases commonly creep on to an areola, late in time, but on the whole satisfactory. Sometimes, however, the occurrence of a sprinkling of small-pox pustules, or the eruption of measles, explains the cause of this irregularity.

3. Now and then there are cases in which the only variety is the complete formation of the areola on the eighth day of vaccination. Where this is the only variety, I presume the future security from small-pox is not affected by it. In eleven cases I have met with a hastened areola on second vaccination, where (the first having totally failed) the operation is repeated on the eighth day of the original inoculation. In a week more, the second punctures have shewn a completed areola, the first punctures having never risen at all. I have noticed this in my former communication on the subject (Med. Gazette, Feb. 15, 1834), to suggest whether it might be supposed possible, that the virus of the first insertion, though not active enough to induce the disease, might, in some way, prepare the constitution for the second, and hasten its course of maturation.

One important thing is still wanting to our estimates of the exact value of vaccination, which is, a fair statement of the proportion of cases of small-pox, mild and severe, occurring after it, amongst a given number of those who have been fully exposed to this contagion at various times, and during several years. This estimate cannot be made in stations for mere vaccination, where the patients (nearly all of them children of the working class, who are constantly changing their abodes) lose all connexion with the surgeon as soon as the disorder produced by it is completed. It would be useful, however, if every practitioner were to make notes of all the cases of small-pox after vaccination, of every degree of severity, that occur within his personal knowledge; but we must look to the inmates of asylums and charitable establishments, to regiments, and generally to those who remain for several years under inspection and control, to be the

subjects of a second and experimental vaccination, by which the proportion and the permanence of the security afforded by the first may be reasonably inferred.—I am, sir,

Your obedient servant,

C. R. Aikin.

Great James-street, Bedford-row,
March 17, 1836.

OBSERVATIONS

ON

CACHEXIA AFRICANA, OR DIRT-EATING.

By F. W. Cragin, M.D.

[Communicated by Professor R. D. Mussey.]

This disease, termed also "mal d'estomac" by the French, is common and too often fatal in the West India islands, and that part of South America known under the general name of Guiana. It is now carrying off numbers in the colony of Surinam with as much certainty as phthisis pulmonalis is in the United States, scarcely a single well-confirmed case being cured; nor is it curable by the common mode of treatment there pursued, from a mistaken view of the pathology of the disease. No age beyond three or four years at the farthest enjoys an immunity from its ravages.

The first symptoms are ordinarily fever at irregular intervals, succeeded by sluggishness, which, as the disease advances, nearly amounts to insensibility. The face, the upper and lower extremities—in fact, the whole external surface, is of an unnatural shining fulness and rotundity, yielding in a slight degree to the impression of the end of a finger pressed strongly upon the part, leaving a depression after the finger is removed. This is especially the case with the feet and ankles, while in other parts no such depression is made; these last approaching in that particular more nearly to the state of elephantiasis than to œdema.

The conjunctiva is of a peculiar snowy whiteness, untinged by a particle of red blood, while the eyes participate in the general fulness, making them appear somewhat prominent, and giving to them altogether a sort of unmeaning yet characteristic stare, which, so far as my observation goes, is peculiar to this complaint. The marble paleness of the lips, of the palms of the hands, and of the soles of the feet, indicates an impoverished state of the blood. The diagnosis may be nearly formed from the pallid appearance of the lips, the gums, and the whole membranous lining of the mouth, and from the condition of the tongue, which in health performs its duty with so much alacrity, lying bleached and bloodless, scarcely able to represent the motives of its owner.

The patient evidently suffers from a sense of cold, as is evinced from an inclination to bask in the sun's rays, even in the hottest part of the day.

There is much palpitation and throbbing of the temporal arteries, while the pulse at the wrist is small, frequent, and slow; quicker, however, after the slightest exercise, after eating, and on the approach of evening.

The secretions are generally diminished; perspiration is suppressed, the urine is scanty, and there is an apparent total suppression of the bilious secretion. Costiveness generally prevails in the commencement of the disease, but in its more advanced stages the alvine discharges are increased in frequency, differing from four to ten or more in four-and-twenty hours, of a thin consistency, and unmixed with bile. In the confirmed and further advanced stages of the disease, a few hours are sufficient after deglutition for the digestion of the food, when it appears in some cases to have undergone a slight, and in other cases no change whatever, in its passage through the alimentary canal. The stools, however, become more watery, dark, and fœtid, as the disease draws to a close.

The appearance of blood drawn from the arm is invariably unnatural; it is thin and watery, of a livid purple hue, assuming neither the bright red of arterial, nor the dark red of venous blood; and wanting the consistency of either, it presents that semiturbid appearance which is a concomitant of a gradual but general decay of the powers of life.

The liver or spleen is generally increased in size, not unfrequently both. The lymphatic glands are enlarged, and frequently indurated; often fifteen or twenty, or even more, of the inguinal glands may readily be distinguished by the feel, and many of them may be seen

* American Journal of Medical Sciences, Feb. 1836.

forming a tumor of no ordinary size in the groin.

Another essential and leading symptom of this disease, is a universally depraved appetite, and an ungovernable determination to the eating of dirt. The only appreciable signs of mental activity exhibited during the course of this disease, are the crafty and cunning plans which the patient most subtilly matures, and as stealthily executes, to procure his desired repast. This consists usually of charcoal, chalk, dried mortar, mud, clay, sand, shells, rotten wood, shreds of cloth or paper, hair, or occasionally some other unnatural substance. Some pick and eat shreds from the garment they wear, till it can no longer be kept upon them; others swallow with avidity the hair which they pick from their own heads, until they are nearly bald before they are detected. Some negroes eat their tobacco-pipes, and those of the other negroes. I was informed by a gentleman of the strictest veracity, that a negro on his plantation was thus morbidly fond of young rats, which he swallowed whole. The man, he had observed, had been declining for some time, and at length declared himself unable to perform his accustomed labour; he was accordingly ordered to the lazaret of the plantation, where the gentleman shortly called to see him; he found him with an empty calabash in his hand, with nausea, pain in the stomach, and a disposition to vomit. After labouring for a moment, he "brought forth" (from the stomach) "a mouse." There was not a single mark of mastication upon the little hairless quadruped, nor had it apparently been many minutes incarcerated; but, probably, being swallowed alive, irritated the stomach, and produced vomiting, by its movements in its last struggles for life. The negro then acknowledged having thus indulged himself, so far as had been practicable, for months.

Peculiar to children under the age of ten or twelve years, and, late in the course of this disease, a state of ulceration often comes on, mostly confined to the cuticle and cutis vera of the feet, legs, and thighs; but sometimes the nates, as well as the hands and arms, are also affected. I seldom had an opportunity of noticing the progress of this ulceration until it had established itself in the true skin. It appears, however, from observation and inquiry, that at the commencement one or more small whitish and nearly round spots are observed about the ankles and feet, which somewhat resemble the first appearance of that also frequent and fatal disease, the "lepra," with which, however, it has no real connexion. The spots in the disease under consideration are of a deadly pale cast, or ash colour, while those of leprosy assume a more lively and cupreous redness. These spots or discolorations become daily more evident, until at length the cuticle gives way; others successively appear, and, advancing in the same manner, also ulcerate. The number of ulcers is, in some instances, very great, from constant accessions, while none are disposed to cicatrize, and in other and very severe cases the whole number does not exceed three or four.

These ulcers gradually increase in circumference and depth, till the cutis vera is penetrated; some of them are at length confluent, others remain unconnected, and in the most loathsome cases, the feet, legs, thighs, and sometimes the nates, present one broad surface of ulcers, some small, and others running into each other, forming patches of greater or less extent.

When this ulcerative process commences, there is frequently mixed with the fæces a small quantity of blood; and in one case which I saw, attended with prolapsus ani, the lower part of the rectum was thickly studded with ulcers, small, but in other respects similar to those situated externally.

These ulcers of the skin are of the indolent kind; they have no raised or bordered edge, and actually discharge but very little, their surfaces being merely kept moistened by a colourless and apparently bland fluid, with no palpable signs of granulation. In this state of the disease the patient becomes more anasarcous, not alone in the extremities, but the whole body, inasmuch that the features, however familiar they may have been, are quite obscured in the general tumefaction.

The diagnosis in this disease is by no means difficult; yet the patient, when accused of dirt-eating, which is too often urged as a voluntary crime rather than an irresistible disease, invariably denies the charge. Under these circumstances it may be necessary to resort to stratagem to detect him in the act, and make him feel and know that further

prevarication is useless. If indigestible substances are swallowed, it is only required to wash the fæcal dejections in water. After frequent rinsings the residual indigestible material decides the point at issue. In Surinam, the result of such a process is frequently a quantity of broken shells. The town of Paramaribo being partially situated upon a bed of marine shells, and the streets and walks of plantations, as well as of the town, being made and repaired with the same material, it is very often seized upon by dirt-eaters to appease that appetite which gives the character to this disease.

As curative means, neither promises nor threats (even when put in execution), nor yet the confinement of the legs and hands in stocks and manacles, exert the least influence, and their preventive effect is as temporary as their employment—so great is the depravity of the appetite, and so strongly are the unfortunate sufferers under this complaint subjected to its irresistible dominion—a metallic mask, or mouth-piece, secured by a lock, is the principal means of security for providing against their indulging in dirt-eating, if left for a moment to themselves; nor does this effect a cure, or save the life of the patient.

The "Dictionnaire des Sciences Médicales," under the head of mal d'estomac, mentions several cases of remarkably diseased appetite; but so close is the connexion, amounting almost to identity, with chlorosis, that it would seem very little was known of the former, as a separate disease, unconnected with the latter.

Dr. John Mason Good also assigns as causes for Limosis Pica, (which he says has been called mal d'estomac, or cachexia Africana,) pregnancy, chlorosis, and some species of mental emotion, and considers it to be a primary affection only when it is occasioned by the vanity of persons who accustom themselves to some empirical material, with a view to improve the form or complexion.

In a work published in London in 1811, entitled "Practical rules for the management and medical treatment of negro slaves in the sugar colonies, by a professional planter," the author, in speaking of mal d'estomac, or dirt-eating, says, "it is the effect of relaxation, and its natural concomitant an impoverished state of the blood, arising commonly from mean diet, and may be produced by any other cause which induces a laxity of the solids." "The power of the passions," he observes, "in producing that effect, is very well known; and we find that negroes labouring under any great depression of mind, from the rigorous treatment of their masters, or from any other cause, addict themselves singularly to the eating of dirt."

Without being competent to remedy the defect in our medical knowledge, I am confident the true causes and means of cure have never been well understood. Many scientific authors who mention this disease have evidently no experimental knowledge of it; and others, who have had opportunities for information, have too generally confined themselves to superficial observation and pre-established opinion.

When we reflect that dirt-eating respects neither age nor sex, there needs no further argument to prove it to be a distinct disease, and in no way connected with chlorosis or pregnancy; and there is sufficient reason to believe that the disposition to eat chalk, clay, earth, and other absorbents, arises from an acidity of the stomach, which is so troublesome in chlorosis and pregnancy, but which—the opinions of others notwithstanding—I have learnt, is by no means a general attendant upon the disease under discussion. From the fact that no age, from a few months, or years at most, is exempt from its ravages, we can neither admit as a cause an accustomed use of empirical materials, nor a melancholic or any other affection of the mind. The effect has been mistaken for the cause. The universal stupor and inertness of the faculties, both mental and corporeal, is an effect of the disease —not a cause arising from a bereavement of friends and home, or joys and kindness: and it may not be amiss to mention the following, one of the many facts that go to prove this position. Persons living on the same plantation, perhaps on the identical section of the same plantation, on which they were born and reared, with all their friends around them, and by indulgent masters and owners, who are themselves the *real* slaves, while the owned are only *nominally* so, provided with ample food, raiment, and, if necessary, medical aid, are also subject to this malady.

The intellectual powers probably suffer in some ratio, depending upon the extent of the disease, and the dominion it obtains over the bodily powers.

As I have observed, wherever the disease is met with, the patient is listless and stupid almost to idiocy, and apparently regardless of comfort, or even of life itself. That superficial observers should look upon this, in adult negroes, recently kidnapped and carried into slavery, as a cause, is not wonderful; but the fallacy of such an opinion is evident from the fact, that this same mental and corporeal torpitude prevails as one of the most prominent features of the complaint, alike in the free and in the bound—in the adult and in the child—in the foreigner and the creole—in the mulatto, mustese or castese, or and in the negro. With regard to the dark spots occasionally observed upon the tongue, resembling spots of ink, they are neither indicative of this nor any other disease—they are perfectly compatible with health, but are seldom met with. They are confined, I believe, to people of colour, and occur as often in the healthy as in the unhealthy, and perhaps depend upon accidental deposits of black pigment, to which is owing the colour of the skin.

How far constitutional peculiarities may predispose to this disease, I am not prepared to say; their influence is probably slight; there are, however, probably few diseases which are not in one way or another affected by various internal and external circumstances, though these are, nevertheless, not considered as causes. I have seen no evidence of its being hereditary. An improper diet is one cause of this complaint, but I knew of instances where the patient was not subjected to such a diet; and, of course, it is not the only cause. Exposure to cold, as from sleeping in damp situations without suitable covering, is another cause.

From the insidious manner in which the disease under notice makes its inroads upon its victims, and the great care they take in concealing it, or, what is more likely, from a general belief that it is irremediable, I have seldom been called (during a practice of nearly five years in Paramaribo) to administer to a patient labouring under this frequent malady until the ulcerative stage had commenced, and the fate of the patient been thereby irrevocably sealed. Many of the cases that came under my view, I met with accidentally, and to most of them it was inconvenient, if not impossible to return. I had, however, determined upon investigating the subject, and ascertaining if it were possible to devise some better mode of treatment than was generally practised. I left the colony soon afterwards, having proceeded but little way in my investigations. Opportunity may again offer, when I shall resume my attention to this disease; and in the meantime, if there can be disclosed a method of cure which is successful, it will enlighten at least one, and not improbably prevent the otherwise premature death of many.

MECHANICAL PHILOSOPHY AS APPLIED TO MEDICINE.

ABSTRACT OF A LECTURE

By Dr. Birkbeck.

Dr. Birkbeck delivered at the Aldersgate school, on Saturday last, the first of a series of lectures on Mechanical Philosophy, considered in reference to the contrivances in the human fabric which are strictly mechanical. He began by stating that a discriminating examination of the varied phenomena which occur in the material universe would suggest a division, in relation to their causes, into three well-marked classes; the first consisting of those events which have an antecedent or cause, immediate and visible, and acting at once for the production of the effect, as we observe amongst the most common occurrences in brute inorganized matter; the second comprehending those events which originate from distant unconnected agency, but respecting the cause of which there exists no more doubt than in the preceding instances,—such are the curvilinear motions of the earth and moon, and the periodical movements of the waters of the earth, all occurring demonstrably by a distinct force, without any cognizable intervening agent; and the third including those movements of animated beings of which the cause is immediate and adjacent, but not in any degree more visible or better understood than the former. It was for the investigation of the instruments by which these undiscoverable causes operate, that these lectures were undertaken.

Man, the Doctor asserted, is unquestionably a machine, but unlike every other machine, in possessing a capability of beginning and continuing motion, and consequently of exerting force, without actual mechanical power. If the arm be now raised by an act of volition, gravity, he observed, is as effectually overcome as by weight or impulse; yet what relation, it may be asked, is there betwixt volition and weight, impulse or pressure? At the same time the vital influence, it must be admitted, although not itself mechanical, is rendered effectual by mechanical means, and the knowledge of such means becomes consequently essential to the clear understanding of the result of vital forces.

The Doctor then proceeded to speak of the mechanical powers, as they are usually termed, or as he should prefer calling them, the mechanical *expedients*, as they could not in any sense of the word have power justly ascribed to them. He stated that six were usually enumerated—*the lever, the wheel and axle, the balance, the pulley, the inclined plane, the wedge*, and *the screw;* but that three—the lever, the cord, and the inclined plane, might be shown to represent the whole. They were, however, each described and exhibited in succession; and the different species of the *lever* with which the description commenced, were detailed, their modes of action described, and the method of calculating their respective powers exhibited. After stating in what cases in common life the three kinds of levers were employed, the action and efficacy of a compound lever was strikingly represented by the large weight and its inconsiderable counterpoise. The *wheel and axle* was shown to be an uninterrupted succession of levers revolving round a common support; and the ratio of the power to the weight, when an equilibrium prevails, was proved to be the same in the radii of the wheel and the axle as that of the two arms of a lever of the first kind. The *balance* was quickly dismissed, as being only employed for the comparison of weights; and the influence of the *pulley* was demonstrated to be assignable to the equal tension of the cord, and where any advantage was obtained, to the mere support of one end, after passing under the sheave or moveable part. More attention was paid to consequences resulting from the interposition of the *inclined plane*, and many instances of its application were given. The common proportions of the power to the weight, when an equilibrium prevails on the plane, were stated; and likewise the useful general ratio, that of the sine of the elevation of the plane to the sine of the angle formed by the direction in which the power acts, and a perpendicular to the base of the plane intersecting it. Respecting the *wedge*, the principal circumstances were brought forward, the opposing opinions as to the relation of its parts noticed, and the paramount influence of impulse, as compared with pressure, particularly insisted upon. The impossibility of calculating the energy of the wedge, without a more perfect knowledge of the influence of percussion on the one hand, and of cohesion, with its varying resistance, on the other, was also fully insisted upon. Lastly, the construction of the *screw* was shown; its prodigious efficacy in consequence of the small distance betwixt two threads, and the great extent of the circumference of the circle described by the impelling lever, —in one instance half an inch to seventy-six inches, or one to one hundred and fifty-two,—and its great utility as a scientific instrument for minute measurement, in the form of the micrometer screw, were fully developed. The importance of the great degree of friction which occurs in its action, as well as in that of the inclined plane and wedge, was briefly mentioned.

After making a few remarks upon the general operation of these expedients, and on their great importance when variously combined to produce different machines, Dr. Birkbeck announced that in his next lecture he would notice the different mechanical processes which are observed in various animals, but especially in the human body.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue a abréger."—D'Alembert.

Histoire Abrégée des Drogues Simples. Par N. J. B. G. Guibourt. 3me. edit. Deux tomes. Baillière.

We notice the appearance of the third edition of Professor Guibourt's admirable

work, in order to recommend it strongly to all those interested in the progress and advancement of pharmacology. It is, in our opinion, decidedly the best and most practical work on drugs and dry-salteries yet published; and must be a valuable acquisition to druggists, and all those of our professional brethren who feel an interest in the history of the materia medica. The present edition contains a considerable quantity of new matter, as must be evident, when we state that it contains nearly 500 pages more than the second edition.

We take this opportunity of noticing and recommending another work on the same subject, though published four years ago, but which, we think, is not known to many; who, were they acquainted with its value, would not be without it. We allude now to the "*Grundriss der Pharmakognosie des Planzenreiches*," by Dr. T. W. C. Martius, of Erlangen. We only regret that the author has confined himself to the *vegetable* materia medica.

Both the above mentioned works are indispensable to all who wish to keep pace with the present state of pharmacological science.

MEDICAL GAZETTE.

Saturday, April 2, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

JUSTICE FROM THE LEGISLATURE.

LORD EASTNOR, on Tuesday, had the delicate task imposed upon him, of presenting to the House of Commons two petitions from very different parties. One was from a Board of Guardians under the new Poor-Law, praying parliament for a favour—the extension of the period for paying a certain loan: the other, calling on the legislature for justice. On presenting the latter petition, his Lordship described it as emanating from sixty-four medical practitioners, of Surrey, who complained, in strong terms, of the hardship to which they were subjected, under the operation of the new Poor Law: they pointed out those grievances which, however familiar to the profession of late, are still, we fear, but too novel to the ears of men in parliament: the district system was exposed—the contract system—the plan of bringing in strangers and young adventurers, to discharge, or rather to try to discharge, the duties devolved upon them as medical attendants of the poor. But above all, the inhumanity of the measures adopted by the guardians was denounced as disgraceful to the country in which such proceedings are countenanced by the legislature. The prayer of the petition was for a committee of inquiry, which, however, his Lordship said he would not urge.

This straight-forward appeal had the effect of bringing the Under Secretary of State, Mr. Fox Maule, upon his legs; when that gentleman informed the House, that in consequence of a late intimation from the Home Department, the Poor Law Commissioners were even now consulting how the grievances complained of by medical men might be remedied. Sir Charles Burrell, and other members, joined in pressing the propriety of speedily finding out some such remedy; and so the conversation ended.

One thing of much importance we learn from this short conversation—namely, that the deputation from Bucks, of the proceedings of which, in their interview with Lord J. Russell, we published a full report in our last, has not been in vain. The protest then presented, and urged on the attention of the noble Lord, seems to have had its effect—the more so, perhaps, as it came upon him with all the charm of novelty, for he said, upon the occasion, "that he had not previously heard of such complaints from any other quarter."

It is so far satisfactory, that the ears

of the proper authorities are at last opened to the just complaints of the large and respectable body of the profession who labour under the grievances of the poor-law system. Nor is it less so, that the Commissioners are now at length really obliged to take the matter into consideration. Hitherto there has been only insult heaped on insult, whenever access was sought to the functionaries in Somerset House; or if an interview were granted, no specific measure of relief was ever promised; the utmost was some indefinite intimation that the thing would be seriously considered. We now know that consideration was *never* seriously given, by the Poor-law Commissioners, to the applications sent to them by medical parties,—the Board of Guardians had it all their own way. This is plain, from the confession made by the Home Secretary, that he had never heard any complaints of the kind before; and that, in short, he had never been consulted on this most serious subject by the worthy Commissioners.

But we trust that medical men throughout the country will not now relax in their efforts, on the supposition, which we fear may be entertained by too many of them, that nothing more remains to be done, the attention of parliament and of government being awakened to their just claims. We can tell them, that in point of securing a final and satisfactory issue in this matter, almost *nothing* has yet been done. Every thing depends upon the exertions now to be made. Every medical association in England ought to follow the example of that of Bucks; and where there is no association yet formed, one ought to be speedily organized, without regard to the audacious dictum of the Poor-law functionaries, who, of course, consider, nay, even venture to denounce, all such social unions as "combinations," in the most opprobrious sense of the word. On this point, however, we leave them in the hands of the protestors of Bucks, whose valuable document (see last Gazette) ought to be attentively perused by every member of the profession.

From the very commencement of this bitter aggression of the rights of medical practitioners, by the local boards, we have pointed it out as the only efficient method of obtaining redress,—to unite — to form associations — to let the grievances be heard—not only by the profession itself, but by the public at large. That end is in some measure attained by the publicity attached to petitioning parliament. But the matter must not rest here: petitions must abound,—petitions must be poured into both Houses from every quarter of the country,—and then the great object—simple justice—will be effected. We cannot sufficiently praise the strenuous exertions of the Bucks Association, nor adequately congratulate them on their success. Deputations of the same kind, wherever practicable, ought to procure interviews with the leading members of the government; and no pains should be spared to secure the assistance of *really* honourable and respectable members of Parliament — for others will do irreparable mischief. We consider at present that no more than the first blow is struck, and that if there be any lack of ardour or energy on the part of those whose bounden duty it is to persevere, all that good that might seem to accrue from "gaining half the battle" will mount aloft to the limbo of vanities.

PATRONAGE OF THE NEW QUACKERY SOCIETY.

As we anticipated, the quacks are delighted with the Lancet scheme of forming an Anti-medical Quackery Society. They say, in their last manifestoes in the Sunday papers, "that they deem it necessary to support the plan

proposed by Mr. Wakley," and that they "have no objection to the title of the society, as projected by him!" This is exactly what we foresaw. What will be the next scheme of the *honourable* Finsburian?

LITHOTRIPSY.

LETTER FROM BARON HEURTELOUP.

To the Editor of the Medical Gazette.

Sir,

I beg the favour of your inserting the inclosed translation of a letter which I have addressed to Sir Benjamin Brodie, on the subject of his correspondence with Sir Charles Bell *. I think I owe to Sir Benjamin a public acknowledgment; and I flatter myself you will second my wish to render what is due to one of the brightest ornaments of your country.

I have the honour to be, sir,
Your obedient servant,
Baron Heurteloup.

4, Queen Ann St., Cavendish Sq.
March 28, 1836.

To Sir Benjamin C. Brodie, Bart.

Sir Benjamin,

A stranger in this land, where I flatter myself I have done some service, I left to *time* the care of answering all those who were opposed to me, or to lithotripsy. I never ventured to hope a defence from so high a quarter.

Allow me to express to you how deeply alive I am to your obliging proceedings, and to assure you, that amidst all the honourable proofs of interest I have met with in this country, the opinion which you have just expressed stands out as one of the highest that I could aspire to. When a man of such eminence as yourself expresses his opinion on a person or on a thing, his word commands attention.

So considered, Sir Benjamin, your letter is not only the act of a "*galant homme*," but it will also be a worthy preface to the serious discussions which lithotripsy demands from the medical profession; for who will venture to speak with levity, and without competent information, on a surgical process to which you, sir, have given your sanction?

But in this letter, destined only to express my gratitude, it would not befit me to introduce questions of science: I will therefore finish by again assuring you of the sense of obligation with which I have the honour to remain,

Sir Benjamin,
Your most obedient humble servant,
Baron Heurteloup.

COLLEGE OF PHYSICIANS.

Monday, March 28, 1836.

Sir H. Halford, Bart., in the Chair.

Some important propositions of a liberal kind were brought before the College on Monday, to which we may at another opportunity advert. The new Council has been elected; the members are as follows:—

Sir H. Halford, *Pres.*

Dr. Turner.	Dr. Chambers.
Dr. Hue.	Dr. Watson.
Dr. John Bright.	Dr. Holland.
Dr. Paris.	Dr. Elliotson.
Dr. Macmichael.	Dr. Clendinning.
Dr. Latham.	Dr. Heberden.

The meeting of Monday evening was thinly attended, perhaps owing to the very unfavourable state of the weather. Two papers were read: the first was one communicated by Dr. J. A. Wilson; it was from the pen of Mr. Russell, and related to *Coup de Soleil*, the pathology of which, so far as we understood the author, consists chiefly in a sudden determination or rush of blood to the lungs. The second paper we subjoin.

On the Pathology of Decapitation. By Edward Rigby, M.D., &c.

The remarkable occurrences which have lately led to the execution of three criminals at Paris by the guillotine, and the minute detail of their last movements, which has appeared in the various daily journals, have excited a sufficient interest in the public mind to render an apology needless for introducing such a subject on the present occasion.

The extinction of life by decapitation presents several phenomena of great interest, not only in a pathological, but also in

a physiological and psychological point of view. I have therefore collected a variety of observations which have been made on this subject in France and Germany, especially by Dr. Fred. Nasse, of Bonn.

That the head after its decapitation must die, is easily explained, both on physiological and psychological grounds; but the question how these changes take place has not been sufficiently investigated.

"As loss of blood and cessation of respiratory changes are the main causes why life ceases in the head, it will be as well to examine the extent and duration of their effects."

From the profuse hæmorrhage which instantly follows a decapitation, it has been commonly supposed that the head dies from sudden loss of blood. This, however, is by no means correct, because the chief of the blood which streams so copiously comes from the trunk, where there is a heart to propel it. We also know that a part may lose a large quantity of blood without its vitality being destroyed. That the head when separated from the body is not suddenly drained of its blood is proved by the following facts:—1stly, We observe in the heads of decapitated animals, as I have proved, says Dr. Nasse, in my own experiments, that the blood does not stream out at once. Repeated observations on decapitated criminals prove that the head does not lose its blood at once (as Burdach has asserted), but gradually. The anonymous author of an essay (published in 1804) on this subject, says that the blood flows from the head slowly. Müller and Bährens state the same opinion. Klein, in the case of a criminal who was executed by the sword, and where he carefully observed the various phenomena presented by the head and trunk, says, "the blood drained very slowly from the head." In another case, he says, "during the whole time that the head was observed, the blood continued dropping from it." In one of these cases the blood immediately after decapitation came away guttatim, and did not flow faster until two minutes and a half afterwards. In the other case it trickled at first, but afterwards ran in a stream. Dr. Nasse found a considerable quantity of blood in the head of a rabbit, after it had been severed from the body a quarter of an hour. On examining the cortical and medullary substance of the brain of a criminal some hours after execution by the guillotine, he found that the vessels contained blood. In another instance, where the head was not examined till some time after execution, the vessels were found empty, but in this case a considerable stream of blood had flowed from the head shortly before it was opened.

The circumstance of blood flowing away shews that it must necessarily have remained fluid in the head; and, moreover, as it flows away gradually, it must have been gradually propelled from the arteries to the veins. Julia de Fontenelle distinctly asserts, that the divided cerebral arteries contracted instantly, and as long as this contraction lasted very little blood was lost.

It is impossible to fix with any degree of certainty how much the cerebral circulation may be diminished, without the functions of the brain being injured; still, however, there are facts which seem to shew that it may proceed to a considerable degree. If Bichat could keep up the functions of the brain in dogs, although he had injected water into the carotids, it shews that a very small quantity of blood must have been present for this purpose. The phenomena of cholera confirm the same fact. The heart may even have ceased to beat in animals, and yet evidences of cerebral life remain. This has been observed in the human subject during a horrible execution related by Bartholin, where the heart had been torn from the criminal, and where afterwards "inter alia tormenta quæ sequebantur, caput expeditè movebat, adstantes torvo vultu intuebatur, et cor suum accuratius contemplabatur donec caput amputaretur."

A rapid extinction of cerebral life might follow the introduction of a quantity of air into the cerebral blood-vessels. Magendie, by injecting air into the carotid of an animal, produced convulsions and death, with symptoms of apoplexy. Air was found in the cerebral vessels of two criminals who were guillotined at Bonn; but this was not until the blood had escaped from them, and is therefore no proof as to what takes place at the instant of decapitation. The complete absence of convulsions which is invariably observed at this moment, shews that no air can then have penetrated into the vessels.

Where a concussion of the brain accompanies the separation of the head from the body, this must, of course, injure more or less its vitality. "Concussion of the brain most frequently follows decapitation with the axe, as the head falls from the height of the block upon the hard floor. Where it is performed with the sword, an assistant usually holds the head by the hair whilst the blow is made. With the guillotine the head falls upon sand, or is received into a bag, so that little or no concussion is produced." In an execution with the sword which I once witnessed, the criminal sat in a chair, and the head was allowed to fall from this height upon the scaffold, although some bandages had been put round, and gathered into a knot

at the top of the head, in order that the assistant might hold it up to the crowd more conveniently.

The degree of irritation which the brain suffers from the injury of the spinal marrow, may be in some degree appreciated by what is observed in animals, where every portion of the neck (spinal marrow included) has been divided, except the carotids; and where artificial respiration has been kept up, the affection of the brain is not very remarkable. If the foregoing observations lead to the conclusion, that there is no reason why life should be instantly extinguished in the head by its separation from the body, can we therefore say precisely until what time are there no signs of death in the head to be discovered? This will evidently appear, sooner or later, according to the degree of vital energy which the head possesses at the moment of separation. As a general answer we may say, that the conditions compatible with a continuance of life in the head, exist until we observe symptoms of relaxation in the muscles of the face, and disappearance of vital turgor in the eyes, by which time the quantity of blood lost from the head will be more considerable. In one of the cases which were observed at Bonn, these appearances were observed in two minutes after the separation of the head from the trunk; in the other they were not ascertained so precisely, as the attention of the observer was directed to other points of interest. Klein, in a case which he observed, did not perceive any motions in the muscles of the face until rather more than three minutes had elapsed; whereas in another case, where the criminal was a woman, and in a state of great debility, they appeared almost a minute sooner. Although we may have no proof of distinct loss of vitality in the head after its separation from the body, another question arises, viz., has the vitality which remains the sufficient degree of energy to generate and keep up the mental life of the head? Numerous experiments prove, that the capability of receiving external impressions, and producing motion in a living part, is very different from the capability of feeling these impressions, and producing these movements in subservience to the will.

To examine this subject psychologically, we must ascertain the state of the mind shortly previous to, and at the moment of, the head being separated from the body. When we take an animal for physiological experiments, we seldom consider its condition, psychologically, at the moment of its being seized, and held fast for the purpose of performing the experiment; and yet this cannot be undeserving of attention: even powerful dogs frequently tremble considerably when laid on the operation table. Two instances have occurred to the observation of Dr. Nasse, of rabbits which had been tied down for the purpose of experiment, and from some reason had been again released, being found dead the following morning, although no cause could be detected upon dissection. It must naturally be supposed that (with very few exceptions) criminals, shortly before their execution, must be in a state of severe mental suffering. Brand, the executioner at Berlin, assured the late Dr. Heim, that of ten criminals whom he had executed, he had scarcely met with one in whom, during the last moments, he could discover perfect consciousness and perception; and that, in most instances, before he had laid hands upon them they were nearly dead. Whether this opinion be correct or not, is of little consequence to our present object; it serves at least to show that, under such circumstances, the last moments must be usually passed in the most painful anxiety.

With regard to the sensation of pain at the moment of decapitation, this must be almost inappreciable: the instantaneous infliction of a wound, whether with a sharp or blunt instrument, is seldom accompanied with much sensation; the degree of sensation is in an inverse ratio to the rapidity of the blow: the almost unconsciousness with which even a whole inferior extremity has been carried away by a cannon-ball, is a striking proof of this fact.

It is well known that motions will take place in parts which have been separated from the body, where every other trace of cerebral action has disappeared: these prove nothing,—they take place without connexion with the will through the brain, and spinal marrow, and are of much the same nature with the movements produced by galvanism. "The mere distortion of the face, in decapitated criminals, proves nothing more as regards the duration of mental action in the head, than those frequently quoted, though rarely observed, cases do, as regards the trunk, where, after the fatal stroke, the hands beat the breast, and the body has made a step." Let us examine some of the phenomena which accompany the act of decapitation :—" One would have thought that the face of the decapitated criminal would have had an expression of great pain; at any rate would have been spasmodically distorted,—on the contrary, it is perfectly composed,—to all appearance, the expression is as completely that of indifference, and without a single distortion of the features, as if nothing whatever had occurred to produce any change. The observations which have been made respecting this fact are so important to our subject, that it will be well worth while to

collect them. The first who observed this remarkable circumstance was Wendt (Breslau, 1803): he says, "I fixed my eye steadily on the decapitated head, but could not perceive the slightest contortion of the face—it was calm, the mouth was closed, the eyes were open and bright, not a feature betrayed the fact of the head being separated from the body." This observation has since been repeatedly confirmed by others. The anonymous author of the essay already mentioned says, "on taking off the bandage from the decapitated head, the eyes were open, bright, quite in a natural state; the physiognomy exactly as it was just before the execution."

In the first case which Klein observed, the head was held before him the instant it was taken off. He could not perceive "the slightest alteration in the features, or distortion of the muscles." In the second case, where he did not see the head till a minute after its separation from the body, he says, "one could almost have fancied that the head wished to finish the prayer (the uttering of which had been cut short by the stroke of the sword); not the remotest expression of pain could be perceived; the countenance was remarkably composed."

Where the lips were in motion during the last moments before decapitation, these movements have been observed to continue after the head was separated. In the case of Mary Queen of Scots, these motions are said to have lasted nearly a quarter of an hour, which is certainly a very considerable period. Klein saw the lips closed, and without any motion, in a head which had been struck off during the act of praying; but then it must be recollected that this head had previously fallen upon the floor of the scaffold, had rolled about, although without coming upon the cut surface, had been taken up, and again let fall. In another case, however, where the head had been also struck off in the act of prayer, the lips were nevertheless closed, and without motion.

Another phenomenon in the muscles of the head after decapitation, is the movements of the eyelids, pupils, mouth, and tongue, which take place quite equably, and without any jerk. Klein has described these appearances minutely, although they had been previously noticed by several authors. They occurred also in the cases which Dr. Nasse observed. These movements come on subsequent to the above-mentioned expression of composure; they appear at first merely to diminish it, and afterwards to remove it.

Cases have been recorded of heads, after decapitation, which had been intentionally or accidentally exposed to any stimulus sufficient to excite the organs of sense, when in a natural state, having manifested such movements of the features as would have resulted from the action of such a stimulus under the usual circumstances. Wendt relates, that having put his mouth to the criminal's ear, and called him by name, the eyes turned to the side from which the voice came. Others have observed the same. According to Julia de Fontenelle, Mojon, Guillotin, Nauche, and Aldini, have all noticed this fact; and he gives a case from his own observation.

As the word "murder" was called into the ear of a criminal who was executed for this crime at Coblence, the half-closed eyes opened wide, and he stared with an expression of astonishment at those who stood before him. Wendt moreover relates, that when the open eyes of the decapitated head were turned towards the sun, they closed. According to Julia de Fontenelle, the same fact was observed in the cases seen by Mojon and his colleagues. According to him, they also observed that when the protruded tongue was pricked with a needle, it was withdrawn, with an expression of pain in the features.

On the other hand, there are many observations to prove that similar experiments have produced no such effects. The ear has been called into without the slightest change of countenance. When a naked lancet was thrust towards the eye, there was no perceptible change, although this was repeated four or five times. Allowing the sun's rays to fall directly into the eyes, produced also no effect. In a case which Senff observed, the eyes did not wink, but remained wide open when the fingers were moved several times before and at them. Klein also remarked, in a decapitated head, that no motion of the eyes was produced by turning the face towards the sun, but that they remained open as before. Eckoldt observed that neither blows, cuts, nor pricking, produced any change in the features of a decapitated head. In a case which Senff observed, where a needle was thrust into the cheek, the expression remained unaltered.

Spontaneous movements have been observed in decapitated heads, which distorted the features, giving them an expression of intense pain; but this has never come on till after the above-mentioned appearance of composure in the expression.

The anecdote of Charlotte Corday's face having blushed after decapitation, when the executioner struck it a blow on the cheek, cannot be quoted, as Cabanis, from the assurance of several witnesses, particularly of a friend who never took his eyes off her, considers the whole story to be a mere fabrication.

Let us now see how the above facts hold good in our present inquiry. The expression of perfect composure in the features

of a head just decapitated, is a circumstance which has been so repeatedly confirmed by observers, that it may be considered as an established fact, although we should naturally expect a contrary result from the mental suffering in which the criminal must be just before decapitation, and the pain he must feel at the instant in cases in which he is still conscious.

This was remarkably the case in a decapitation with the sword at which I was present. The first blow failed, having been struck deep into the shoulders; not a muscle of the face or the body stirred, although it required a considerable effort to disengage the blade. A second blow, better aimed, severed the head from the shoulders. The features, when the head was held up, were perfectly composed; the expression of wretchedness which had been so strongly marked on the criminal's face but a few seconds before had quite disappeared,—the blood merely dropped from the head.

The cases where the face, before execution, had betrayed a marked expression of suffering, which ceased instantly afterwards, are well worthy of notice. This quiescent state of the features cannot result from paralysis, because there would be complete relaxation of them. Convulsive action would be marked by distortion, of which there is not a trace. The question is, what is the condition produced by decapitation which is accompanied with this insensibility to pain?

The fact that the lips of Mary Queen of Scots moved for a considerable time, is no proof of mental life continuing after decapitation. The slight movements of the features which come on spontaneously after decapitation, so completely unite the appearance of spasm with that of mental expression, that it has given rise to very different opinions.

Klein says, that he could not consider the motions of the mouth, tongue, and eyes, as any thing more than spasmodic action, although more superficial observers might have taken them for evidences of mental life. "The mouth," says he, opened somewhat, then closed, and opened again, during which the tongue protruded a little, although not beyond the lower lip. The eyes turned gently outwards, then inwards, so that if I had been inclined to take one view of the question, I could have almost said, the head is looking at the bystanders, and would say something." We must look upon the mental character of these movements as very doubtful;—firstly, because a period of from one and a half to two minutes elapses after decapitation, before they take place; and secondly, because they are accompanied with a protruding of the tongue, which decidedly looks more like convulsion than voluntary motion.

The distortions which frequently, if not always, take place in the features, shortly after the separation of the head from the trunk, in all probability are convulsions. They come on after the period of composure in the features, and in three cases were observed after the slight movements of the eyes, mouth, and tongue, as above described, and may also be produced by irritation applied to the remaining portion of the spinal marrow.

It is a remarkable fact with respect to the convulsion which appears in the head after decapitation, that nothing of the sort is seen in the body. This is an observation which the executioner Brand made to Dr. Heim, of Berlin, and which has also been confirmed by Klein. This was also remarked in the bodies of the two criminals which were guillotined at Cologne and Coblence. We may explain this fact, when we recollect that the head is decidedly the part most exposed to excitement just before the execution; that the blood is not expelled so rapidly from the head as from the body; and that in the human subject the head may be safely asserted to possess more vitality than the body.

In comparing the various results together, Dr. Nasse comes to the following conclusions. First, that the conditions necessary to a continuance of vitality in the decapitated head do not instantly cease. Secondly, it has been observed that there is an expression of composure which does not indicate paralysis, as also movements which, from their correspondence with each other, make it probable that there must remain, for a certain period, a degree of conscious mental activity in the head.

It will now be necessary to examine the different effects produced on the head, *psychologically* speaking, according to that part of the neck at which the separation has taken place. In the criminal who was guillotined at Coblence, in whom evidences of hearing appeared to exist, the neck had been severed deep between the 6th and 7th cervical vertebræ; whereas, in the case at Cologne, where this appearance was not observed, the instrument had gone through the 5th vertebra. The result of other cases does not confirm this fact, symptoms of hearing having been manifested where the separation had taken place at the 4th vertebra. Klein, moreover, observed the composed expression of the features, in cases where the separation had taken place between the 3d and 4th, and even between the 2d and 3d vertebræ.

From the foregoing researches, we find that the phenomena presented by the head immediately after its separation from the body, occur also in a state which comes on under similar circumstances to those of decapitation.

It has been observed, in people who have been exposed to overpowering emotions of the mind, especially fear, that a remarkable change in the relation between the mind and body is produced. The mind is no longer sensible of injuries done to the body: however violent they may be, the mind remains perfectly unaffected. Although they are thus, as it were, separated, yet impressions of the higher senses appear to reach the mind. It produces movements which have all the appearance of being voluntary—a state materially differing from that of insensibility.

The late Dr. Heim, of Berlin, the acuteness of whose observations is well known, collected several instances of this affection. If we compare this state with that of the head after decapitation, we shall perceive a remarkable similarity. The cases which Heim has published give sufficient evidence that this trance-like condition may occur in persons who were in a state of perfect health. Violent emotion of the mind precedes the one as well as the other condition. The observations of the executioner Brand shew that, with very few exceptions, criminals are in a state of the greatest fear just before execution. If we could suppose that a person, with all the preparations for a violent death before him, could be devoid of fear, the pain of the execution being now so much greater, would be sufficient to induce this state, which the mental suffering, before the stroke, had failed of doing.

To all appearance, the sensation of pain ceases completely in this state which we are comparing with that of decapitation. A patient who has been in this condition has no recollection of having suffered pain. It would seem, in this state, that the will still continues its control over the voluntary muscles, from the circumstance that, in spite of the great bodily suffering to which the body was exposed in Dr. Heim's cases, no convulsions were observed.

The chief difference between these two conditions is, that in the one the normal state can return; in the other, of course, it cannot. How long a condition of this sort can last in the head, after its separation from the body, can only be determined approximately. Klein, as before mentioned, observed the quiescent state of the features, in three instances, to last from one and a half to two minutes. Future opportunities must determine these interesting facts, where the observer shall be so situated as to entirely concentrate his attention, without the slightest interruption, upon the phenomena exhibited by the head.

LECTURES

ON THE

DISEASES OF THE NERVOUS SYSTEM.

By M. Andral.

As published in the *Gazette des Hôpitaux*, with the approval of the learned Professor.

HYPERTROPHY AND ATROPHY.

Hypertrophy of the Brain, Cerebellum, Spinal Cord — Atrophy of the Brain: General, Partial—Atrophy of the Cerebellum—Atrophy of the Spinal Cord.

The diseases comprehended in the second class of cerebral affections may be divided into four orders—viz. hypertrophy, atrophy, induration, and softening.

I. *Hypertrophy of the nervous centres.*—This requires to be carefully distinguished from hyperemia. The two affections may take place together or separately, presenting different symptoms accordingly. The disease does not attack all ages indifferently, as we shall see in the sequel.

The principal anatomical character of hypertrophy is the remarkable density of the nervous substance. The colouring part of the blood seems present in diminished quantity, being just the reverse of what we find in hyperemia. If the cerebral mass be sliced, it is found to be dry; and this dryness exists both internally and externally. The convolutions are closer, and the infractuosities less apparent. The ventricles seem disposed to become obliterated. Thus hypertrophy may be traced in the principal parts of the nervous centres—1, in the brain proper; 2, in the cerebellum; 3, in the spinal cord.

In the brain both hemispheres may be affected by the hypertrophy, either throughout or partially. When it is general, either the parietes of the cranium become developed simultaneously with the brain, and then no particular mischief occurs; or the cerebral mass being alone attacked, the bones retain their ordinary dimensions. Under this latter condition numerous symptoms supervene, dependent upon compression, and upon the congestions to which this secondarily gives rise.

Among the causes of this hyperemia has been enumerated too early exercise of the

intellect; but this requires proof. Age seems to have some influence, inasmuch as the disease is usually met with between the ages of 20 and 35: beyond this it is rare. The symptoms may be altogether wanting when the skull becomes proportionally developed; but where it is otherwise, disturbances manifest themselves in the intellect, in motion, and in sensation. The intellect becomes dull; there is a kind of idiocy, which progressively increases with the hypertrophy. In some there is merely perversion of intellect. This lasts for a longer or shorter time, when delirium usually occurs: the disturbance quickly becomes general, and the patients die. Sometimes profound coma attends this stage. Headache is usually one of the predominant symptoms; and in certain cases there is also delirium.

The lesions of movement consist in convulsions, particularly in infants; and in some patients they assume every appearance of epilepsy. In the autopsies of some epileptic subjects, I have traced the complaint to well-marked hypertrophy of the brain. Occasionally paralysis takes place, and this may succeed to the most violent convulsions. Loss of sensation sometimes, either gradual or sudden, has been observed; and it is so far remarkable, that, in a chronic affection such as this, the loss of sensation is sometimes so sudden, as to become complete within a single day. Although the functions of organic life are not in such cases the most apt to be affected, yet digestion and circulation are occasionally implicated in hyperemia.

The disease may present two distinct periods—one acute, the other chronic. In the first we observe violent convulsions; and in addition to the symptoms above alluded to, we may have those of acute hydrocephalus. In the second we witness nearly the same phenomena—convulsions, occasional delirium, the symptoms of chronic hydrocephalus, and epilepsy. At this period the patients sometimes die, amid the mischiefs produced by the acute form of hypertrophy. As to the duration and termination of the disease, although the intensity and extent of the affection will necessarily render them variable as to time, yet the ultimately fatal result is but too certain.

As to treatment, nothing can be done in reference to the hypertrophy itself; every thing consists in treating the symptoms.

II. *In the cerebellum* we have the same characters as those already stated with regard to the brain. The disease may be latent, or manifest itself externally by the development of the corresponding part of the cranium. Has this development any connexion with increased action of the generative system? M. Voisin, in examining the heads of many criminals, states that he has, by the existence of the above development, been able to tell those who had been guilty of rape.

The cerebellum may even overcome the resistance which its bony covering presents, and form a true hernia. M. Lallemand relates a case of this nature.

III. *In the spinal cord* there may be hypertrophy throughout its whole extent (of which two cases only have been recorded), or in some particular portion. There is a case of a child who had the brain but little developed, but who, as a kind of compensation, had the spinal cord very much increased in size. Laennec has related a similar case, but without stating what the symptoms were.

We may readily understand how, in cases where there is hypertrophy of the nervous centres, a degree of congestion, otherwise unimportant, may prove fatal.

Atrophy of the nervous centres.—Two kinds of this may be distinguished: the one congenital, resulting from original defect of the organs, and called *agenesie;* the other acquired, and consisting in smaller volume of the parts, whether preceded by an antecedent natural condition, to which a diminution succeeds, or consisting in the growth of the parts being arrested at a certain point. It is scarcely necessary to observe, that in either variety the atrophy presents itself in very different degrees.

As to the anatomical characters, the nervous substance is pale, while its density is sometimes augmented and sometimes diminished. Round the seat of the disease there are certain changes, which implicate either the membranes or the bones. When the membranes are affected there is usually an increased quantity of serum, which is destined to fill the void which would otherwise occur from the entire or partial absence of substance at the seat of the atrophy. According to M. Magendie, the effused fluid is contained within the arachnoid membrane; at other times it is within true cysts, formed either exterior to or within the cerebral substance. In some cases the bones become moulded to the shape of the brain, and there is then less serosity. The bones, however, may be entire, and yet the brain be too small to fill the cavity, and then we find thickening of the membranes, exostoses, &c. It is also sometimes found that the cranium has become thickened at the expense of the inner table; and this, of course, is only discovered after death, when the head is opened.

It occasionally happens, that although the brain be but little developed, or even be wanting, the size of the head is greater than is natural. Under these circumstances the bones have become thickened at the expense of the external

table, or else they are attenuated and rendered almost membranous; they are distended by a mass of serous fluid, which fills them completely, and constitutes hydrocephalus. In the same manner are to be explained the herniæ of the meninges through the parietes of the cranium, even when there is atrophy of the brain, or of some portion of it: these herniæ have also received the name of hydrocephalus.

The causes are by no means always the same, or perfectly known; some, indeed, affect the fœtus in utero. The brain may be arrested in its growth, at any given point, by deficiency of nutritive power, and then an abundant secretion fills the space which it ought otherwise to have occupied. The meninges may, in consequence of an affection of which they are the seat, attract the nutritive process to themselves, or they may throw out too large a quantity of serum, and thus compress the brain, so as to produce atrophy. In such a case the cerebral mass may be altered rather in its form than its nature, and may present a perfect brain in miniature. Tumors formed within the cranium, cysts, such as those resulting from apoplexy, and all the causes of compression of the brain in general, may be enumerated among those of atrophy: other causes, again, operate by producing inflammation or irritation.

The atrophy is not equally frequent in all the parts which compose the nervous centres; and it also varies much in degree.

Atrophy of the brain.—Both hemispheres may be wanting, in which case extra-uterine life is impossible; or there may exist only some feeble traces of brain, the rest being made up of a spongy cellular and vascular mass. One hemisphere may be wanting: this has been met with several times, and the extra-uterine life is then very short. Any of the lobes may be wanting, particularly the anterior, in which case the intellect has been sometimes ordinary, and sometimes weakened. Once, hemiplegia of the opposite side was observed; in another instance there was a remarkable difficulty of speaking.

Both anterior lobes may be deficient, and with this there is usually, though not invariably, flattening of the forehead, for the space may be occupied by fluid. The state of the intellect, under such circumstances, has been scarcely observed, as the infants generally die very early: but in one case, where a girl lived to be fifteen years of age, she was an idiot. The power of motion has sometimes been abolished, and sometimes only weakened. Sensation has also been variously altered: in one instance vision was annihilated, a fact difficult to explain, except on the general principle of the close connexion of the parts of the brain with each other. The sense of smelling has more than once been wanting. Both middle lobes have been absent, and where this happens the phenomena are similar to those above related. So also the posterior lobe, as well as the middle, has been discovered to be wanting. This occurred on the right side; the intellect did not appear to have suffered, but there was hemiplegia of the opposite side.

The posterior cornua of the lateral ventricles have, in two instances, been known to be wanting, without any defect in the rest of the brain; it was attended with idiocy, but without any morbid affection either of sensation or motion.

General atrophy.—An example of this was presented by an individual who shewed nothing remarkable in the way of symptoms, except that he had epilepsy; and the case is curious when contrasted with that in which epilepsy was coincident with hypertrophy of the same organs.

Partial atrophy.—This may be limited to one side, where we find some of the convolutions hard, withered, wasted; at other times it is the deeper parts which become atrophied. The white parts may be the seat of this affection, without always exhibiting appreciable signs of disease. It may well be supposed that in these cases we shall sometimes meet with appearances just opposed to those of hypertrophy, such as thinness of the cranium. Paralysis of the opposite side, as well as obtuseness of intellect, are sometimes met with.

The corpora striata and the corpus callosum are susceptible of atrophy, but there is no instance of it in the fornix. The pineal gland has been sometimes found extremely small, without there being any corresponding symptoms; in some cases, however, its atrophy has been said to be coincident with idiotcy. A case of atrophy of the tuber annulare has been met with, and it has been observed that there was the same affection of the left anterior pyramid, and that all the other parts of the encephalon were in their natural state. The alteration of these parts had given rise to hemiplegia and entire dumbness, notwithstanding that the tongue retained its mobility unimpaired; the intellect had not suffered. These facts are given on the authority of M. Cruveilhier.

The brain, as is well known, diminishes in size in proportion as age advances; and it is worthy of remark, that in these cases the pia mater becomes filled with serosity. The cerebellum, a singular circumstance, is not subjected to the same law. According to M. Desmoulins, the weight of the brain at 70 years is less by one-twentieth than at adult age.

Atrophy of the cerebellum.—This may be a true *agenesie*, which has only been observed once, without there being at the same

time deficiency of other parts: on the other hand, this disease may be merely the effect of imperfect development. In one case simultaneous absence of the pons varolii was witnessed, the space usually filled by the cerebellum being occupied by serosity. A girl, aged 11, who died at La Charité, was the subject of this affection, from which she had at first suffered nothing. Bluntness of intellect, taciturnity, sombreness, and an increasing weakness of the lower extremities, supervened; she was then confined to bed, epileptic convulsions came on at intervals, after one of which she died. Sensation and the special senses presented nothing remarkable. The digestion was good, but the disposition of the child fretful. The genital organs were fully formed; and what is worthy of remark, there was a disposition to masturbation.

The cerebellum may be diminished in size throughout, as I have seen in one case; and this condition may be appreciated by the external surface of the bones. In this case the genital organs were but inconsiderably developed. One lobe of the cerebellum may be in a state of atrophy, with a corresponding state of the testicle of the opposite side. Gall has given examples of this, without stating what was the condition of the intellect. Atrophy of the cerebellum may result from the pressure exerted upon it by certain tumors, producing disturbances analogous to those above described. According to Gall, castration is not without its influence on the size of the cerebellum.

Of three cases of atrophy of the cerebellum, with the same lesion of the lateral half of the brain, epilepsy was observed in one; but ought not this phenomenon to be rather referred to the alteration of the brain? With a smaller development of the cerebellum, or of one of its lobes, an hypertrophy of the spinal cord has been seen. An exalted state of the sensibility of the skin was in this case general, but particularly at the soles of the feet, which could not be touched without exciting acute pain.

Atrophy of the spinal cord.—This, like atrophy of the brain or cerebellum, may be complete, and then there can be no extra-uterine life. In such case different states of the spinal cord have been remarked, such as the absence more or less complete of its bony parietes, or their excessive increase, or, lastly, they may be in their natural state. The spinal cord itself is susceptible of many degrees in the imperfection of its growth. Thus it has been found intersected with one, or even with two, canals in its interior. The grey substance may be wanting, or may exist alone, the nerves remaining entire. Again, atrophy of the spinal cord may consist in a simple diminution of bulk, either general or partial. When general, it is easily detected on post-mortem examination; but when partial, it may escape observation. The bulb of the cord may be alone affected; and M. Cruveilhier says that in a case of this kind the bulb was converted into grey matter, and indurated, there being no other change. The symptoms were great difficulty of speech, progressively increasing difficulty of respiration and deglutition, with death by asphyxia. The intellect was undisturbed. In general, atrophy of the spinal cord gives rise to paralysis, the intensity of which goes on increasing.

Treatment.—The hopelessness of this is unhappily too notorious. The nervous centres, whatever may be the perfection of their development, are subject to other diseases besides those of which I have hitherto spoken; such are softening, and induration.

ROYAL INSTITUTION.

Friday, March 25, 1836.

Insect Anatomy, and the Oxy-hydrogen Microscope.

Mr. Goadby this evening gave a very interesting account of the anatomy of insects, illustrated by dissections made by himself, and shown by an improved portable oxy-hydrogen microscope, on a disk ten feet in diameter.

The improvements which Mr. Goadby has introduced into this instrument are twofold. In the first place, a parabolic mirror, made of speculum metal, and 3½ inches in diameter, is substituted for the condensing glasses; so that the only glasses employed are object glasses, and these are doublets, namely, two plano-convex lenses. The other improvement consists in the substitution of bags for metallic gasometers, the bags being made of sheet Indian rubber, protected externally by a surface of cloth.

The objects shown were numerous. The first was the skeleton of the *Blatta americanus*. The skulls of several insects were also shown. The perfect bug (*Cimex lectularius*) was also shown, and its mode of feeding described. This disgusting parasite is said to have reached England in the wood required to rebuild London after the great fire. It would appear that he instantly possessed himself of the freedom of the city, and notwithstanding the efforts of individuals who have dared to dispute his rights, he has pertinaciously

remained a citizen to this hour. But there are some curious particulars connected with his mode of feeding. He possesses a jointed rostrum, in which are contained four fine lancets or bristles, and having inserted the point of the beak (or rostrum) into the skin, he makes four deep punctures with the lancets, which are then retracted into the head, leaving the beak as a tube through which the blood of his victim may flow in a continuous stream until his hunger be satisfied. To prove that the rostrum itself is inserted, you have only to let a bug feed on the back of your hand when the skin is loose, and while he is feeding clench your fist so as to tighten the skin, when the animal will in vain attempt to disengage himself; neither can he do so until you once more open your hand. Now if you watch the feeding with a lens, you will perceive the blood flowing up the tube into the œsophagus in a constant steady stream. Not so with the gnat; for although he too carries a tube containing lancets, the mode of feeding is essentially different; his lancets are not *retracted*, but may be seen working up and down the tube like a piston in the barrel of a pump, obeying the impulse of that extraordinary organ of his, the sucking stomach, which is dilatable at the pleasure of the insect, in such a manner as to draw the food into the œsophagus.

The eye of the beetle, *Prionus longimanus*, was beautifully exhibited, shewing the almost innumerable facets, of which Lewenhoeck counted 55,088 in the two eyes of the dragon fly. The flexor and extensor muscles of the common cricket (*Acheta domestica*) were well shewn; and the enormous power which the extensors have over the flexors; so that the insect may be easily propelled to a considerable distance.

The structure of the feet of insects was admirably exhibited; for example, the tarsus of the *Locusta viridissima*, with its eight fibro-elastic cushions, analogous to those of the feline tribe; the foot of the *Asylus crabriformis*, with two suckers, which enable the fly to walk up smooth surfaces, and against gravity; foot of *Tabanus bovinus*, with three such suckers; foot of *Dyticus marginalis*, with innumerable suckers, mounted on short tubes.

The wings of insects of the Linnæan orders formed striking objects. There were exhibited the wing-case and wing of the Coleoptera; ditto, Hemiptera; ditto, Lepidoptera; wings of Neuroptera; wings of Hymenoptera. There is in the structure of the wings of this latter order a remarkable peculiarity, and one which the lecturer said he had never observed noticed in print, which is, that the inferior edge of the *superior* wing possesses, in one part of its course, a broad, deep fold; and that the upper edge of the *inferior* wing is provided with a number of hooks, varying from 20 to 35 in number, which attach themselves to the fold of the upper wing; so that in the action of flight, the two wings strike the air only as one broad wing. From the result of his observations, Mr. Goadby is induced to regard this structure as an additional character of the hymenopterous insect, never having known it to fail. There was also exhibited the wing of *Volucella pellucens*, a dipterous wing, exhibiting the so-called *winglet*. With regard to this latter peculiar appendage of the Diptera, it has been said by some authors, that nature had attempted to confer four wings on insects of this class, but did not succeed, and so left the rudiments of a pair, which have hence been called *winglets!* "When I dissected off," said the lecturer, "the beautiful wing which now appears before you, I thought I could detect some connexion existing between this *winglet*, and the vesicular air-bag which occupies from about the second ring of the abdomen to the base of the wing; and when I found that the wing-bones of insects, like the wing-bones of birds, are so many hollow tubes, through which large air-tubes are distributed, containing a quantity of condensed air, thus rendering *them* also specifically lighter than the atmosphere, I came to the conclusion that these *winglets* had something to do with this process—that they were, in fact, auxiliaries, and on examining the winglets themselves, I find them to be merely capacious sacs. I do not assert that their use is just what I have described, but I do throw it out as a hint for the careful investigation of others: that the wing-bones are not only *hollow*, but *permeable*, I can give proof, as I have injected them with oil of turpentine, and the effect is very complete."

Among other objects exhibited with great success, were the sting with the poison-bag, secreting glands, and excretory duct, of the honey bee; and the alimentary canal, with salivary glands and hepatic vessels, of *Locusta viridissima*; alimentary canal with the enormous salivary apparatus of the caterpillar (*Cossus ligniperda*); stomach of *Blatta* (cock-roach) shewing the six teeth at the pyloric extremity; stomach of the larva of the dragon-fly, shewing the four teeth at the pyloric extremity; proventriculus of cricket, shewing the six horny bands, to which the teeth are attached.

Mr. Goadby next called attention to a most magnificent object—the respiratory system of the caterpillar of *Cossus ligniperda*, or the goat-moth, as dissected by himself. We decidedly think that this

admirable piece of dissection stamps Mr. Goadby as perhaps the ablest practical insect anatomist of the day.

Our space is nearly filled—yet we must endeavour to find room for the following remarks of the lecturer.

There are three modes by which insects breathe,—by spiracles, by air-tubes, and by branchiæ. The terrestial insects, throughout their phases, breathe by spiracles or stigmata; a number of oval mouths, very conspicuous on the rings of caterpillars, and which open at once into the trachæ.

Of the aquatic insects, some breathe by air-tubes (larvæ of gnats, for instance), which are placed at the caudal extremity, and are connected with the tracheæ; others, such as larvæ of ephemera, by gills placed at their sides.

The muscles of the abdomen are also respiratory muscles, for when the abdomen is contracted, the air contained in the air-tubes is expelled, and on the expansion of the abdomen the atmospheric air rushes in.

The air-tubes consist of three coats; a mucous coat, around which is twined an elastic spiral cord, which forms the second coat, and is necessary to keep the tube always open, and to this circumstance they owe the name of tracheæ, from their resemblance in use and structure to the cartilaginous rings of the trachea of man; the third and last coat consists of a membrane, transparent, smo th, hard, and generally colourless, which loosely invests the tube, and is readily detached from it.

The respiratory organs of insects are by far the most extensive structures: there is not a muscle, a nerve, a single lens of their very compound eye, but is furnished with an air-tube, and they are distributed in amazing quantities to the alimentary canal. It would appear thus how important to them is free respiration, and nature has bestowed great pains to secure it to them: the external spiracles of the perfect insect are so carefully concealed as to elude ordinary observation, while those of caterpillars, conspicuous as they are, have the protection of hair to prevent the entrance of extraneous substances—particles of dust, &c.—while within we see the most extensive anastomosis prevail, connecting by the most direct course the spiracles with the tracheæ, and the tracheæ themselves connected at each extremity, so as to form but one immense circulating pipe; and hence the difficulty of destroying life, for if you succeed in stopping up every spiracle *but one*, that will be sufficient to carry on the respiratory process; somewhat tardily, it is true, but quite sufficiently for the purpose of sustaining life.

BATH PETITION TO PARLIAMENT

FOR

REMUNERATION TO MEDICAL WITNESSES

ATTENDING CORONERS' INQUESTS.

To the Editor of the Medical Gazette.

Sir,

Inclosed is a copy of a Petition to the House of Commons, from this city, in favour of the Bill for remunerating medical witnesses for their attendance at coroners' inquests, sent to Mr. Warburton last evening, to be by him presented to the House*. It was signed by eleven physicians, and fifty-five general practitioners. If you would give it place in your widely circulated Gazette, you will oblige your readers in this city.—I am, sir,

Your obedient servant,

George King.

3, New King Street, Bath,
March 25, 1836.

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament assembled.

The humble Petition of the undersigned Members of the Medical Profession, residing in the City of Bath and its Vicinity:

Sheweth,

That your Petitioners, in common with the entire Medical Faculty, besides the ordinary and inevitable demands on their time, are more subject to extraordinary inroads on their professional and other engagements than any other branch of the community: they are, moreover, from the very nature of their profession, further liable to the frequent and great inconvenience of a summons for their attendance at the inquest of a Coroner, in cases of sudden or accidental death.

That on these occasions, besides the immediate and serious inconvenience alluded to, much of their valuable time is frequently occupied either in giving professional evidence of facts, in elucidating circumstances, or in the performance of difficult and hazardous post-mortem examinations; and this accompanied, sometimes, by a troublesome chemical analysis.

That, as the ability to perform these duties is not acquired without a considerable sacrifice of time, money, and the most intense application of mind, your Petitioners respectfully submit, that qualifications so attained are as much the private property of the possessor as any other species of acquirement, and are equally

* It was presented on Tuesday evening, the 29th.

entitled to the protection of the laws; your Petitioners are, however, not only unremunerated on these occasions for the arbitrary appropriation of their time and professional skill, but are without any legal claim whatever on the Coroner, or other authority, for compensation.

Your Petitioners therefore humbly pray your Honourable House, that the Bill now in progress for remunerating Medical Men for their attendance at Coroners' Inquests may receive the sanction of your Honourable House.

And your Petitioners will ever pray, &c.

REMUNERATION OF SURGEONS IN THE MERCHANT SERVICE.

To the Editor of the Medical Gazette.

Sir,

Glancing over the papers to-day, I observe an advertisement from a ship for New South Wales, which recals to my mind circumstances, the detail of which may interest, and amuse, those of your readers who may be intended for the merchant service. Feeling inclined to see other parts of the world, about two years and a half ago I applied to the captain of this same ship to be appointed his surgeon: he expressed himself fully satisfied with my testimonials, and anxious to have the benefit of my knowledge. He informed me that the voyage would last about twelve or fifteen months, and proposed as an adequate remuneration *twelve pounds*—fourteen being his ultimatum! The voyage has continued until two years and a half have expired, and it is very evident that the fourteen pounds would have been the largest amount I should have received. The profits, it must be confessed, would have been enormous. Surely such an occurrence as this,—such an insulting proposal,—ought never again to be made: it is one of those subjects which require the interference of parliament, to the full as much as attendance at inquests.

I have the honour to be, sir,
Your obedient servant,
F. F. F.

March 29, 1836.

AMENORRHŒA.

Dr. Schlönlein, late Professor of Medicine at Würzburg, is of opinion that an injection of aloes (ten grains in a small quantity of warm water), thrown up the rectum at the time the menses ought to make their appearance, is more certain in its effects than any other emmenagogue.—*American Journal.*

NEW PAMPHLET.

Quackery: its danger, irrationality, and injustice: the causes of its success; the best means for its suppression. Addressed to all classes (by Dr. Cowan, of Bath).—pp. 18.

NOTICES.

We have to apologize to several correspondents, for whose papers, this week, we could not find room.

Dr. Lendrick's letter in our next.

We doubt if we can give insertion to Mr. Weiss's communication,—it savours so strongly of the advertisement.

Erratum.—In the account of the "Interview of a Deputation of the Bucks Medical Association with Lord John Russell," in last number, page 1036, first col., first line, *for* "partially," *read* "patiently."

LECTURES ON MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

By Jon. Pereira, Esq., F.L.S.

Lecture XXVIII.

METALS AND THEIR SALTS.

The last series of substances belonging to the inorganized kingdom, which I have to examine, is that containing the *Metals;* which bodies may be very conveniently arranged for our purpose in three classes, as follows:—

Class 1*st*, containing the *electro-positive metals*, the oxides of which form alkalies, or earths. *Potassium, sodium, barium, calcium, magnesium,* and *aluminum*, are the only metals of this division which enter into the composition of the mineral materia medica.

Class 2*d* includes the *electro-negative metals*, or those which form, by preference, acids when combined with oxygen. The substances of this class which I shall notice, are *arsenicum* and *antimony*.

Class 3*d* contains those *electro-positive metals* whose oxides are neither alkalies nor earths, but which perform the functions of electro-positive elements in saline combinations. *Silver, mercury, copper, bismuth, tin, lead, zinc,* and *iron*, will be here spoken of.

I propose to notice these different substances in the order here laid down; and, therefore, I begin with potassium.

POTASSIUM.

General remarks.—This metal was discovered by Davy, in 1807, and received its name in consequence of being the base of potassa. It is obtained either by galvanising moistened hydrate of potash, or by exposing potash to an intense heat along with iron filings or charcoal. It is a silvery white metal, distinguished from all other metallic substances by its great lightness, (its specific gravity being only 0·865 at 60° F.),—by its taking fire when thrown on water, and burning with a red-coloured flame, and forming potash,—and by the green colour of its vapour. The symbol for it is K, the initial of *kalium*, one of the synonymes of potassium.

Native state.—This metal is found in both kingdoms of nature. Thus *sulphate, nitrate*, and *silicate* of potash, and *chloride*, (perhaps, also, the *iodide* and *bromide*) of potassium, are met with in the inorganic kingdom: while *carbonate, phosphate, sulphate,* and *nitrate of potash*, and *chloride of potassium*, with many other salts of potash, are found in the organized kingdom.

Characteristic tests.—The potash salts are recognised by the following characters: the hydrosulphurets, ferrocyanurets, and carbonates, produce no precipitates with them. Tartaric, perchloric, and carbazotic acids, occasion precipitates of the bitartrate, perchlorate, and carbazotate of potash. Chloride of platinum produces a yellow precipitate, composed of the chloride of platinum and chloride of potassium, which is, therefore, called the chloroplatinate of potash. Lastly, the potash salts communicate a violet tinge to flame.

Pharmacological preparations.—The following compounds of potassium are employed in medicine, and, therefore, will require to be spoken of:—

1. The *protoxide of potassium* or *potash*, its *hydrate*, and saline combinations, called the *oxy-salts of potash*.

2. *Iodide of potassium.*
3. *Sulphuret of potassium.*

Hydrate and Solution of Caustic Potash.

History.—Solutions of the caustic alkalies, were, doubtless, procured by the Greeks and Romans. Paulus Ægineta, and Geber, have both directed how they are to be prepared. Black, however, in the year 1756, first distinguished, chemically, the caustic alkalies from their carbonates.

Synonymes.—Potash has been known by various names; such as *kali* and *vegetable alkali.*

Preparation.—To prepare caustic potash, add some fresh burned lime to a solution of the carbonate (commonly called the sub-carbonate) of potash. In the London Pharmaeopœia, the proportions employed in the manufacture of *liquor potassæ* are, one pound of the carbonate, half a pound of lime, and a gallon of water. The theory of the process is simple: the lime takes the carbonic acid from the carbonate, setting the potash free, which dissolves in the water.

Re-agents.	Results.
$\dot{K}\ \ddot{C}$	$\dot{K}$
$\dot{Ca}$	$\dot{Ca}\ \ddot{C}$

To separate the carbonate of lime, the liquid is to be filtered, and then forms the *liquor potassæ* of the shops, which has been also termed *lixivium causticum*, or *potassa pura liquida.* The filter should be of cotton or linen, as paper and woollen are readily decomposed, and care should be taken, during the filtering, to exclude the air as much as possible.

If the liquor potassæ be evaporated to dryness in an iron pot, and the residual mass fused and cast in moulds, we obtain the *fused hydrate of potash*, called in the Pharmaeopœia, *potassa fusa*, and formerly termed, *cauterium potentiale, lapis causticus,* or *fused caustic kali.*

Sometimes, to render the potash less deliquescent, slacked lime is added to the solution of potash before it is evaporated to dryness. By this means we obtain a mixture of hydrate of potash and lime, called in the Pharmaeopœia, *potassa cum calce.*

Properties.—The *fused potash* of the shops is usually more or less coloured (brownish, greyish, or bluish), in consequence of the presence of foreign matters, especially iron; for pure hydrate of potash is white. It is soluble in water and alcohol; and during the solution in water heat is evolved. At a low red heat it fuses, and at a higher temperature is volatilized. Its specific gravity is 1·706.

Liquor potassæ is a limpid, colourless, odourless liquid, of an acrid taste. If quite pure, and free from carbonic acid, it will not effervesce with sulphuric acid, nor become milky by the addition of lime water; but as it strongly attracts carbonic acid from the air, it is rarely met with sufficiently pure to stand the last-mentioned test. If the solution should be free from carbonic acid, but contain lime, the production of milkiness by a little carbonate of potash will readily detect this latter body.

Characteristics.—Potassa fusa and liquor potassæ may be easily recognized as potash preparations, by the tests already mentioned. That they are preparations of *caustic* potash is shewn by their strong alkaline re-action (for example, permanently reddening turmeric, and rendering infusion of cabbage, green)—by not whitening lime water, or effervescing on the addition of a strong acid—by their soapy feel—and by the solubility of the solid potash in alcohol; for the carbonates are insoluble in this liquid. Alumina is soluble in caustic potash, but not so in the carbonate.

Composition.—Pure anhydrous potash is composed of—

1 atom potassium ······	40
1 atom oxygen ········	8
1 atom potash ········	48

Its symbol is $\dot{K}$. The *fused*, or *hydrate of potash*, consists of—

1 atom potash ········	48
1 atom water··········	9
1 hydrate of potash ····	57

Its formula is $\dot{K}\ \dot{H}$.

Frequently this substance contains a little peroxide of potassium.

The strength of the *liquor potassæ* may be determined by its specific gravity. A pint of that prepared according to the directions of the London Pharmaeopœia is said to weigh sixteen ounces, or 7680 troy grains. Now a wine pint of distilled water weighs 7292·3 Troy grains, and hence the specific gravity of this liquor is 1·0531; for—

7292·3 : 1000 :: 7680 : 1·0531.

Here is an extract from Mr. Dalton's table, shewing the strength of solutions of potash of different specific gravities:—

Atoms.		Potash per Cent. by weight.	Spec. Gravity.	Boiling Point.
Potash.	Water.			
1	8	39·6	1·47	265°
1	10	34·4	1·42	246
		26·3	1·33	229
		19·5	1·23	220
		13·	1·15	215
		9·5	1·11	214
		4·7	1·06	213

From this you will observe, that if the liquid had the specific gravity 1·06, 100 parts would contain 4·7 of potash; and, therefore, if the Pharmacopœial solution were pure, it would consist very nearly of—

Water	96
Potash	4
	100

Physiological effects.—In the concentrated form (as the *potassa fusa*), the local operation of caustic potash is exceedingly energetic. The alkali, of course, neutralizes any free acid in the part, and decomposes whatever ammoniacal salts may be present, causing the evolution of ammoniacal gas. Its chemical action on the organized tissues is most powerful, as may be well illustrated by experiments. Thus if you rub a little potash solution between the fingers, you experience a soapy feel, and by continued action the epidermis is corroded and dissolved. If we take a piece of fibrine (muscle, for example), and digest in a potash solution, an unpleasant ammoniacal odour is evolved, a little alkaline sulphuret is formed, and the fibrine is dissolved; the compound of fibrine and potash thus formed, may be termed *fibrate of potash.* The addition of an acid precipitates the fibrine somewhat altered in its properties, and combined with some of the precipitant, so that if the sulphuric acid had been employed, we should obtain a kind of *sulphate of fibrine.* The same kind of effect is produced by the action of potash on albumen: thus, this substance unites with the alkalies to form soluble compounds, which may be termed *albuminates.* Gelatine is also readily dissolved by alkalies, with the deposition of any phosphate of lime which it may contain. These phenomena are to a certain extent comparable to those of saponification. You see, then, that the caustic alkalies form soluble compounds with substances which enter largely into the composition of the organized tissues, and, therefore, you are prepared to admit the probability of Orfila's statement, that the alkalies are, of all corrosive poisons, those which most frequently perforate the stomach. For the intestinal mucus readily dissolves in alkalies, whereas it is coagulated by acids; so that the former are much more quickly brought in contact with the living tissues, which resist, for a certain time, the chemical influence of the caustics, but the affinities being powerful, the vital properties soon cease to offer opposition—the part dies—and then the alkalies commence their action on the tissues, which they speedily dissolve. Hence, if a large quantity of potash were swallowed, you would expect the most violent symptoms, though of the same general kind as when the mineral acids have been taken.

When small, or therapeutical doses of the solution of potash are administered, the first effect must be the neutralization of the free acid of the stomach, and which, according to the experiments of Dr. Prout, is the hydrochloric; so that we should then get a chloride of potassium formed. I do not pretend to know what can be the particular use of this acid in the digestive process, but presume, as it is a constituent of the healthy gastric juice, that it serves some important purposes; and I therefore can readily believe that the continued employment of an alkali, even in small quantities, must injure the assimilative process, by altering the chemical properties of the healthy ventricular secretion. Experience seems to prove the correctness of these *à priori* conclusions.

If the quantity of potash swallowed be more than sufficient to neutralize the free hydrochloric acid, but insufficient to have any chemical action on the living tissues, it acts as a slight irritant, increases the secretions of the alimentary canal, becomes absorbed, and alters the qualities of the fluids secreted, more particularly those of the urine. Thus Magendie has found, by the exhibition of alkalies to dogs, not only that the natural acidity of the urine was destroyed, but that this secretion was even rendered sensibly alkaline. Moreover, the modification thus produced in the quality

of the renal secretion, is accompanied by an increase in its quantity, so that the alkalies rank among our most powerful diuretics—an effect which may be, in part, owing to the local stimulus which they communicate to the secreting vessels, in their passage through them.

By continued use the alkalies give rise to increased activity of the different secreting organs, and of the absorbing vessels and glands; effects which are analogous to those caused by mercury. After some time the digestive function becomes disordered; the appetite fails; the blood is said to become thinner, and to lose its power of spontaneous coagulation, when drawn from the body; the whole system, but more particularly the digestive organs, becomes enfeebled; and a state precisely similar to that of scurvy is brought on. It is said, if the alkalies be temporarily suspended the blood speedily reacquires its coagulability, but loses it again when we resume their employment. These phenomena deserve notice in connexion with scurvy,—a disease which is brought on by the use of agents well calculated to give an alkaline property to the system, namely, salt, salted provisions, and animal food;—while the remedies most useful in the treatment are such as neutralize alkalies—namely, acids, or vegetables which readily generate acids. It appears to me, therefore, in the highest degree probable, that scurvy, and the effects caused by the employment of the alkalies, are both dependent on the same condition.

Uses.—Caustic potash is employed for various purposes in medicine, the principal of which I will enumerate. In the first place, it is sometimes used as an *escharotic*, though in this respect it is not free from objection; for its great deliquescence occasions some difficulty in localizing its action. For the production of an issue, however, it may be employed, but we must proceed thus:—Apply to the part one or two layers of adhesive plaster, in the middle of which is an aperture of the exact size of the intended issue. Then moisten the *potassa fusa*, or the *potassa cum calce*, and rub on the part until discoloration is observed. Wash, and apply a linseed meal poultice; and when the eschar is detached, insert the pea. In bites by poisonous animals, as venomous serpents, mad dogs, &c. this escharotic may be used with advantage. Mr. Whateley recommends the *potassa fusa* as the agent for arming caustic bougies to be applied in strictures of the urethra, but the practice appears so dangerous, (particularly on account of the deliquescence, and violent action of the caustic) that I believe it is now rarely, if ever, resorted to. There are many other cases in which this substance may be used, but which it is hardly necessary for me to enumerate. I shall only instance the destruction of warts and fungoid growths of various kinds, and the opening of abscesses, more especially in the groin; but for the latter purpose, I should always prefer the lancet.

(*b.*) As an *antacid* we resort to the *liquor potassæ* in various affections of the digestive organs, which are attended with an inordinate secretion of acid, known by the acid eructations, cardialgia, and other dyspeptic symptoms. It must, however, be evident, that the neutralization of the acid is merely palliative. But I think that the continued employment of alkalies frequently diminishes the tendency to acid secretion, though when the use of the remedy is suspended, this tendency generally returns. Commonly you will find that the cases calling for the employment of alkalies are those benefited by tonics, and hence I believe the alkali is, in most cases, best given in some mild bitter or tonic infusion; such, for example, as the infusion of gentian, or of quassia; the sulphate of quinia oftentimes disagreeing with the stomach in these cases, besides which it would be decomposed by the alkali. The beneficial effects of alkalies are said to be particularly observed in those forms of dyspepsia which result from the inordinate use of spirituous liquors.

Of course the liquor potassæ would equally neutralize acid which may have been accidentally or purposely swallowed, but it is rarely given for this purpose, on account of its irritant qualities, and because many other agents (as chalk, magnesia, and soap) are equally efficacious as antacids, while they are free from the objections which exist in these cases to the use of the caustic alkalies.

(*c.*) *To modify the quality of the urine*, liquor potassæ is a most valuable agent. I have already mentioned, that by the employment of alkalies, not only may the natural acid of the urine be destroyed, but even an alkaline property be communicated to it; so that whenever the secretion of lithic acid, or of the lithates, is inordinate, the alkalies present themselves to our notice as chemical agents for counteracting this condition. It has been supposed by some, that the efficacy of the caustic alkalies, in preventing the deposition of lithic acid gravel, consists in their holding it in solution; an explanation inconsistent with the fact, that the carbonated alkalies and magnesia are equally efficacious, though they are incapable of dissolving it. We are, therefore, led to the conclusion, that the alkalies actually prevent the formation of this acid, or neutralize the free acid in the urine, which is the immediate cause of the precipitation of the lithic acid; whether by an action on the

digestive organs or otherwise, we know not. In resorting to these agents in urinary deposits, you must be particular to avoid employing them when there is any tendency to the deposition of the phosphates. The phosphate of lime, which naturally exists in the urine, is held in solution in this liquid by some acid, as seems proved by the fact, that the addition of a caustic alkali precipitates it. Berzelius thinks the acid is the lactic, an acid which you will perhaps recollect I have already mentioned as probably performing the same office in the milk of animals. But I confess that the experiments of Mr. Brett, lately detailed in a very excellent paper in the MEDICAL GAZETTE, appear almost conclusive that carbonic acid is the solvent. The nature of the acid is to my present purpose, however, of secondary importance: it is admitted by all that the solvent is an acid, and that by the use of alkalies this acid may be neutralized, and the urine rendered alkaline. Now what will be the necessary consequence of this? Obviously the deposition of phosphate of lime; so that you observe the use of alkalies may actually cause the appearance of *white sand* in the urine; and in patients predisposed to its formation you may increase its quantity. You see, then, the important bearing these facts have on practice. "I have known," says Mr. Brande, "soda water exhibited in a case of stone in the bladder, *produce* abundance of white sand, which the ignorance of the patient and his medical attendant led them to refer to the solvent power of the medicine upon the stone, which they thought was gradually giving way and being voided; whereas, great mischief was doing, by giving the urine more than its usual tendency to deposit the phosphates, and, consequently, to augment the size of the calculus." In the treatment of the lithic acid diathesis, remember that the use of alkalies is, to a certain extent, a palliative mode of treatment, and, to be successful, must be conjoined with other means of cure. On this subject, indeed, I cannot do better than recommend to your attentive perusal Dr. Prout's work.

(*d.*) *In gout.*—It has long been known that some pathological relation exists between gout and lithiasis, though the exact nature of the relationship has not been made out. We know, for example, that gouty subjects are exceedingly prone to the formation of large quantities of lithic acid—proved, not only by the frequency of lithic acid deposits in the urine, but also by the gout stones or lithate of soda: and hence the remedies found useful in the one have been tried in the other complaint. This has led to the employment of alkalies in the treatment of gout.

(*e.*) The alkalies have lately been said to produce very beneficial effects in those *inflammations* which have a disposition to terminate in exudation and adhesion—that is to say, those that frequently give rise to the formation of false membranes, or of adhesions; such, for example, as croup, pleurisy, and peritonitis. If experience should subsequently confirm the assertions already made respecting their efficacy, we shall have another analogy between the operation of these alkalies and of mercury. Theoretically, it has been argued, the alkalies are likely to be beneficial in these diseases on two accounts; first, they have a tendency to diminish the supposed plasticity of the blood, which some have assumed (though without proof) to be connected with the exudation; and, secondly, we find these albuminous deposits readily dissolve, out of the body, in alkaline liquids. You must not, however, be led away with reasoning of this kind. In conclusion, I would just add that Eggert recommends the alkalies as specifics against croup; though Sundelin found them inoperative. Hellwag employed them to cause the removal of the deposited lymph; Memminger gave them with benefit in hooping-cough; Mascagni, in pleurisy and peripneumony. It is asserted that in the latter complaints the alkalies render the expectorated matter less viscid, and at the same time act powerfully as diaphoretics and diuretics.

(*f.*) In *induration* and *enlargement of the glandular system* the alkalies have also been recommended; for example, in bronchocele, mammary tumors, affections of the testicle, diseases of the mesenteric glands, induration of the liver, salivary glands, &c. I have seen the liquor potassæ remarkably beneficial in excessive enlargement of the lenticular or glandular papillæ at the base of the tongue.

(*g.*) In *syphilis* and *scrofula*, also, the alkalies have been employed with advantage. Some of the most obstinate and troublesome forms of the venereal disease frequently occur in scrofulous subjects, in whom mercury will not only be useless, but absolutely prejudicial. In two or three cases of this kind I have seen the liquor potassæ, taken in the compound decoction of sarsaparilla, of great benefit. Though scrofula may be relieved by the use of alkalies, there is no ground for believing that they have any power in curing this malady, as some have asserted.

(*h.*) The alkalies have been employed as *diuretics in dropsy*, especially when this disease arises from glandular enlargements, or other causes likely to be relieved by these remedies.

(*i.*) There are many other diseases in which the alkalies have been recom-

mended; but which I shall place together under one head, as I have barely time to enumerate them. In those *skin diseases* which are scaly (as lepra and psoriasis) the internal employment of the liquor potassæ has been found serviceable. In *chronic rheumatism*, as an emmenagogue in *uterine complaints*, and in some chronic *diseases of the lungs*, the alkalies have likewise been employed. Sometimes a very dilute solution of potash has been used as a *stimulating wash* to ulcers; and Dr. Paris tells us that Hannay's celebrated nostrum, the *Preventive Wash*, was nothing more than a solution of caustic potash.

Administration.—The mode of employing the *potassa fusa* in the making of an issue I have already described. For internal exhibition, the liquor potassæ is used in doses of from 10 drops, gradually increased to the extent even of a drachm, carefully watching its effects. It may be administered in the infusion of orange-peel. Table beer is said by Dr. Paris to disguise completely the nauseous flavour of the alkali; but of course if the beer be at all sour, the acid will neutralize the alkali, and render it inert as an antacid. Veal broth is another liquid for its administration, and we are told that Dr. Chittick's nostrum for the stone was the fixed alkali in this liquid.

Antidotes.—In poisoning by the alkalies, the antidotes are either acids or oil, both of which form salts with the alkalies, and diminish their causticity. Chereau prefers oil, which should be given to the extent of several pounds. Vinegar, lemon or orange juice, even the very diluted mineral acids, should be resorted to, if oil be not at hand.

Carbonates of Potash.

Three *carbonates* of potash are known, namely, the *carbonate* (which by way of distinction may be called the *mono-carbonate*), the *bicarbonate*, and the *sesquicarbonate*. Of these, the two first only are employed in medicine.

1. *Monocarbonate of Potash.*

History and synonymes.—This salt must have been known for a long period, though it was at first confounded with the carbonate of soda. In the eighth century, Geber showed how it might be procured, namely, by burning cream of tartar, dissolving the residue in water, filtering, and evaporating. It has been known by various names, such as *salt of tartar*, *mild vegetable alkali*, *fixed nitre*, and *subcarbonate of potash*.

Native state.—It is well known that carbonate of potash may be obtained in abundance from the ashes of plants, but it does not follow that it previously existed in the plants themselves; since it may be formed during the process of combustion, by the decomposition of other salts of potash, the acids of which are of a vegetable nature. The acetate, malate, and oxalate, (principally the first) are those salts which most probably yield the carbonate, when vegetables are burned. If, however, the circumstance mentioned by Mr. Parkes in his Chemical Essays be correct, in one case at least, the alkaline carbonate exists ready formed in the plant. He says, that some of the poor weavers of Yorkshire press out the juice of fern, and use it in the place of alkali, in the cleansing of cloth, at the fulling mills.

Preparation. — Carbonate of potash may be obtained from *wood ashes*. These, for the sake of economy, are principally procured in those countries rich in forests, such as America, Russia, Sweden, and Poland. For this purpose wood piled up into heaps is burned, either on the surface of the ground, or in pits dug for the purpose. The ashes thus obtained usually contain potash, soda, lime, magnesia, oxide of iron, oxide of manganese, silicic, carbonic, and phosphoric acids, and chlorine. They are lixiviated with water, which dissolves the carbonates, sulphates, and silicates of potash and soda, and the chlorides of potassium and sodium; and the solution being poured off from the undissolved matter, is evaporated in large iron pots, by which means a dark-coloured mass is obtained, called *rough potashes*, *cineres clavellati crudi*, or by the French, *salin*. The dark colour is said by Dumas to be owing to the *ulmate of potash*.

I may here remark, that the *ulmic acid* of this ulmate is formed during the combustion of the wood; it is an acid composed of—

30 atoms of carbon	.... =	180
15 atoms of hydrogen	.. =	15
15 atoms of oxygen	.... =	120
1 atom ulmic acid	.... =	315

By calcining potashes in a reverberating furnace until the dark colour is destroyed, we obtain *calcined potashes*, or *cineres clavellati calcinati*, called in the Pharmacopœia *potassa impura*, and usually known in the shops by the name of *pearl-ashes*. By this process the ulmic acid is decomposed, and, in consequence, the ulmate transformed into the carbonate of potash.

Pearl-ashes have frequently a red, green, or bluish tinge, the first depending on the presence of peroxide of iron, the second and third on the manganesiate of potash, which is always formed when pearl-ashes con-

tain manganese, and are heated to redness in contact with the air.

Pearlashes consist, for the most part, of the carbonate of potash, but mixed with sulphate and silicate, and also with chloride of potassium. Vauquelin analyzed some American pearlashes, and obtained the following products:—

Sulphate of potash	80
Chloride of potassium	4
Potash	754
Carbonic acid and water ..	308
Insoluble matters	6
	1152

In the Pharmacopœia you will find a process for the purification of pearlashes (which are called *Potassa impura*). It consists in dissolving 3 pounds of the salt in $3\frac{1}{2}$ pints of water, filtering, and evaporating in a copper (in the Pharmacopœia it is directed to be iron) vessel, the liquor being stirred, so that the salt may be granulated. The product is the *potassæ subcarbonas* of the Pharmacopœia, sold in the shops under the name of *salt of tartar*. As you will anticipate, this process does not give us a pure salt, for sulphate and silicate of potash and chloride of potassium may be readily detected in it, though the quantity is not usually very large, and therapeutically, the impurities are of little or no importance.

The high price of pearlashes has led to the manufacture of subcarbonate of potash from *sal enixum* (the bisulphate of potash), by heating it in a reverberatory furnace with charcoal. This yields sulphuret of potassium, in consequence of the carbon deoxidizing the bisulphate. By roasting, the sulphuret is decomposed, and converted into the carbonate of potash; the sulphur being dissipated, and the potassium oxidized and combined with carbonic acid from the fire.

Properties.—The *potassæ subcarbonas* of the shops is white, granular, and inodorous. Its taste and reaction on vegetable colours (as turmeric, and red cabbage infusion) are strongly alkaline. It is fusible at a red heat; has a strong affinity for water, so that by exposure to the air it attracts water, and becomes liquid, forming the *oleum tartari per deliquium*. It is very soluble in water; and in the Pharmacopœia is an officinal solution, called *liquor potassæ subcarbonatis*, composed of 1 pound of the salt dissolved in 12 fluid ounces of distilled water. The solution is colourless, and has a specific gravity of 1·446.

Pure carbonate of potash may be prepared by the combustion of cream of tartar and nitre, (forming what is called *white flux*), lixiviating, concentrating by evaporation, and crystallizing. The primary form of the crystal is a rhombic octahedron. This salt is insoluble in alcohol.

Incompatibles.—Most salts (except the neutral salts of potash and soda) are decomposed by carbonate of potash. I need hardly say acids are incompatible with it.

Composition.—The granulated carbonate (or subcarbonate) of the shops consists of about—

84	parts of the carbonate of potash.
16	parts of water.
100	

But when properly crystallized, its composition is—

1 atom carbonic acid	22
1 atom potash	48
2 water	18
	88

And its symbol is $\dot{K}\ \ddot{C}\ \dot{H}^2$

Impurities.—The nitrate of silver may be employed to detect the chloride salts,—the chloride of barium to recognize the sulphates present. To distinguish the silicic acid, supersaturate with hydrochloric acid, evaporate, and heat to redness: then lixiviate. The silicic acid is insoluble in water.

Characteristic tests.—It is known to be a carbonate by effervescing with the strong acids, and by a solution of it causing a white precipitate with lime water, soluble in acetic acid. That it is a potash salt, is determined by the tests for potash already mentioned. From the bicarbonate of potash it is distinguished by its precipitating a solution of sulphate of magnesia.

Physiological effects.—Its effects are precisely of the same kind as those of caustic potash already described, but much milder, on account of the presence of the carbonic acid, which diminishes the alkaline properties of the base. When it is taken into the stomach in large quantities, it acts as a powerfully caustic poison, —sometimes inducing death in twelve hours, and producing symptoms similar to those caused by the mineral acids: sometimes, however, the patient recovers from the immediate effect of the alkali, but in consequence of the altered condition of the alimentary canal, the assimilative process cannot be carried on; and after dragging on a miserable existence for a few weeks, the unfortunate sufferer dies of absolute starvation. And lastly, in some cases the caustic operation of the poison is principally confined to the œsophagus, causing stricture and death. In one case, related by Sir Charles Bell, the patient lingered with this disease for twenty years! I must refer you to Dr. Christison's work on Toxicology, for a more

detailed account of the poisonous operation of this substance.

Therapeutically, also, the carbonate of potash acts in a manner precisely similar to caustic potash, except that it is milder. It would, therefore, be tedious to go over this ground again.

Uses.—We employ this salt in medicine in most of the cases which we have already mentioned as adapted to the use of the caustic potash. For example, as an antacid in dyspeptic affections; in that form of lithiasis which is accompanied with an increased secretion of lithic acid, or the lithates; in those forms of inflammation in which there is a tendency to the formation of false membranes; in gout, &c.

Externally, it has been used in the form of a solution applied to wounds; as an injection in gonorrhœa; as a collyrium in some affections of the cornea, &c.

Lastly, the subcarbonate of potash of the shops is sometimes employed in the manufacture of the common effervescing draught, made with either the citric or tartaric acids.

20 grains of subcarbonate of potash are saturated by .. { 18 grains of citric acid, 18 grains of tartaric acid, or ℥iv. of lemon juice.

Administration.—It may be given either in the solid or liquid state. In the solid state it is given in doses of from gr. x. to to ℨss. The solution of the Pharmacopœia may be given to the extent of a drachm, or more.

Antidotes.—When swallowed as a poison, the antidotes are oils or acids, as already mentioned for the caustic alkali.

2. *Bi-carbonate Potash.*

History, synonymes, &c.—This is the salt called in the Pharmacopœia the *carbonate;* and by druggists frequently termed *aerated kali.* It was first prepared by Cartheuser, in 1752.

Preparation.—In the Pharmacopœia it is ordered to be prepared by passing a stream of carbonic acid through a solution of the carbonate. The operation is readily effected in a Woulfe's apparatus. The solution is then to be filtered, evaporated, and crystallized. I believe, however, all the salt of commerce is prepared by the following process:—Dissolve 500 parts of carbonate of potash in 1000 parts of distilled water, and then add gradually 300 parts of pulverized carbonate (or rather sesquicarbonate) of ammonia; apply a gentle heat until the ammoniacal gas is nearly all driven off; then filter and crystallize.

Theory.—Subcarbonate (or rather carbonate) of potash, I have already mentioned, is, as met with in commerce, an impure salt, one of the foreign ingredients being silicic acid. When carbonic acid is passed through the liquid, each atom of carbonate takes an additional atom of carbonic acid, and becomes bi-carbonate, the silicic acid being at the same time deposited.

In the second process, the volatility of the ammonia, joined to the affinity of the carbonate of potash for more carbonic acid, causes the decomposition of the sesqui-carbonate of ammonia: the ammonia with a small portion of carbonic acid is disengaged, while the remaining acid converts the carbonate into the bi-carbonate of potash.

Properties.—It is a crystalline solid, the primary form of whose crystal is, according to Mr. Brooke, a right oblique-angled prism. It is inodorous, has an alkaline taste, and re-acts very feebly as an alkali on vegetable colours. It is soluble in water, but is almost insoluble in alcohol. When exposed to the air, it undergoes no change. When exposed to a red heat, it gives out half its carbonic acid, and becomes the carbonate.

Composition.—It consists of

2 atoms carbonic acid	=	44
1 potash		48
1 water		9
		101

Its symbol, therefore, is $\dot{K}.\ 2\ddot{C}.\ \dot{H}$.

Characteristic tests.—The same as for the carbonate already described, from which it may be distinguished by its not precipitating a solution of sulphate of magnesia.

Impurities.—The substances likely to be present are the chloride of potassium, and sulphate of potash. The first may be recognized by nitrate of silver, occasioning a precipitate insoluble in nitric acid; the second by chloride of barium, producing a white precipitate insoluble in acids and alkalies. If any carbonate of potash, (that is, the sub-carbonate of the shops) be present sulphate of magnesia will occasion a white precipitate.

Incompatibles.—The incompatibles are the same as for the last-mentioned salt.

Physiological effects.—The effects of this salt are similar to those of the last, except that its local action is much less, in consequence of the additional atom of the carbonic acid, while the alkaline effect on the system is equally energetic, so that it is an exceedingly eligible preparation in lithiasis, and other cases where we want its constitutional, and not its local, action. You observe, then, that in proportion to the

quantity of carbonic acid in combination with the alkalies, the less powerful are they as local agents.

Uses.—I need not say any thing on the uses of this salt, since, with the exception of those cases where we employ caustic potash as an escharotic, we may use this salt, and frequently, indeed, with more advantage. In the production of effervescing draughts, it is commonly employed; the proportions to be used for this purpose are as follows:—

20 grs. of bicarbonate of potash will saturate $\begin{cases} \text{15 grains of citric acid,} \\ \text{15 grains of tartaric acid, or} \\ \text{ʒiijss. of lemon juice.} \end{cases}$

Where there is great irritability of stomach. I believe the effervescing draught made with this salt and citric acid, to be more efficacious than that made with carbonate of soda and tartaric acid, the citrate of potash being, in my opinion, a much milder preparation than the tartrate of soda.

Administration.—This salt may be given in doses of from gr. x. or gr. xv. to the extent of half a drachm, or even a drachm.

Sulphates of Potash.

Three sulphates are described—the *sulphate* (which by way of distinction may be called *monosulphate*), the *bisulphate*, and the *sesquisulphate*. Only the two first, however, are employed in medicine.

1. *Bisulphate of Potash.*

History and synonymes.—This is the salt called in the Pharmacopœia the *supersulphate of potash*, and which is known in the shops by the name of *sal enixum*, and was formerly termed the *acid vitriolated tartar*, or the *sal auri philosophicum*.

Preparation.—It is prepared by dissolving the salt left after the distillation of nitric acid, filtering the solution, and crystallizing. It is also a product of various other manufactures.

Properties.—It is crystallizable, the primary form of the crystal being either a right rhombic prism, or the rhombic octahedron. It has a very acid taste, and reacts strongly as an acid on vegetable colours, and decomposes the alkaline carbonates with effervescence. It is soluble in about twice its weight of cold water.

Composition.—It consists of—

2 atoms sulphuric acid ... =	80
1 atom potash	48
2 atoms water	18
	146

Its formula, therefore, is $\dot{K}\ 2\dddot{S}\ 2\dot{H}$.

Characteristic tests.—The presence of sulphuric acid may be recognised by the chloride of barium; while the potash may be recognised by the characters already mentioned for this substance. From the mono-sulphate of potash, it is distinguished by its acid taste, its action on litmus and the alkaline carbonates, and by its greater solubility.

Physiological effects and uses.—It is rarely used as a medicine. The excess of acid renders its local operation that of an astringent. When swallowed, it operates as a mild purgative, and may be employed in the same cases as the sulphate, over which it has the advantage of greater solubility.

Administration.—The dose of it is from gr. xv. to ʒij.

2. *Monosulphate of Potash.*

History and synonymes.—The mode of preparing this salt was taught by Croll in the early part of the seventeenth century. It has been known by various appellations, such as *vitriolated kali*, *vitriolated tartar*, *sal polychrest* (literally signifying, *salt of many uses or virtues*), *sal de duobus*, &c.

Native state.—Sulphate of potash is found both in the inorganised and organised kingdoms. In the first, it has been met with in some mineral waters of Saxony and Bohemia, in native alum, in alum-stone, and in a mineral called polyhalite,—in which Stromeyer found no less than 27·6 per cent. of the sulphate. The following are some vegetable substances said to contain it,—the root of Polygala senega, Winter's bark, the bulb of garlic, myrrh, opium, &c. The blood and urine of man also have it.

Preparation.—It may be prepared by adding lime, or its carbonate, to the bisulphate of potash, by which sulphate of potash and sulphate of lime are procured. In the Pharmacopœia we are ordered to obtain it by saturating the bisulphate with the carbonate of potash.

Properties.—It crystallizes in pyramids, the primary form of which is the right rhombic prism. It is unchanged by exposure to the air, or to moderate heat. At 60° F. it requires sixteen times its weight of water to dissolve it: in alcohol it is insoluble.

Composition.—It is an anhydrous salt and consists of—

1 atom sulphuric acid .... =	40
1 atom potash	48
	88

Its symbol is $\dot{K}\ \dddot{S}$

Characteristics. — I have already mentioned these, when speaking of the bisulphate.

Physiological effects. — It acts as a very mild purgative, without occasioning any heat, pain, or other symptoms of irritation. Its operation is, in fact, too mild for ordinary use.

Uses.—It is particularly serviceable as a laxative, in disordered conditions of the alimentary canal, as diarrhœa and dyspepsia. It is best given, as I believe, in combination with rhubarb. Thus, from five to ten grains of rhubarb, with from fifteen grains to two drachms of this salt, will be found to act mildly and efficiently in diarrhœa. The objection to its use is its slight solubility.

Nitrate of Potash.

History.—At what time this salt became known is difficult now to determine. As it is found in various parts of the East, on the surface of the earth, it appears probable that it must have been known at a very early period. But the terms *νίτρον* and *nitrum*, which occur in the writings of Theophrastus and Pliny, seem to have been applied either partially or exclusively to *natron* (sesqui-carbonate of soda). As I cannot spare time to enter fully into this historical discussion, I must refer those who feel interested in the subject to the learned and elaborate article in Beckman's "*History of Inventions and Discoveries.*" The word *saltpetre*, usually applied to nitre, is evidently derived from *sal petræ*, literally signifying, rock salt.

Native state.—This salt occurs in both kingdoms of nature. In the East Indies, Egypt, Persia, Spain, and other parts of the world, large quantities of it are found in the soil, sufficient, indeed, to pay the expense of extraction. It would appear to be formed below, and is brought to the surface of the soil by efflorescence. Some have thought that the nitric acid of the salt was formed by the union of the nitrogen and oxygen of the air, while others have supposed the presence of some animal matters were necessary to yield, by their decomposition, the nitrogen. In opposition to the last view, however, I may state that in a nitre cave at Ceylon, Dr. Davy found nitre, although there was no animal matter. The potash of the nitrate is in most cases easily accounted for, being found in some of the constituents of the soil, namely, feldspar and mica.

Nitrate of potash is met with in various plants; for example, in *cissampelos pareira*, *geum urbanum*, *parietaria*, *hemlock*, the *sunflower*, &c.

Artificial nitre.—Observation and experience having proved that nitre is annually formed in some countries, attempts have been made to imitate nature's processes, and, as we shall find, with success. In giving you some account of these experiments, I cannot resist quoting a few lines from Dr. Thomson's "*History of Chemistry.*" At the commencement of the French Revolution "all the great powers of Europe combined to attack France, assisted by a formidable army of French emigrants assembled at Coblentz. The Austrian and Prussian armies hemmed her in by land, while the British fleets surrounded her by sea, and thus shut her out from all communication with other nations. Thus France was thrown at once upon her own resources. She had been in the habit of importing her saltpetre and her iron, and many other necessary implements of war: these supplies were suddenly withdrawn; and it was expected that France, thus deprived of all her resources, would be obliged to submit to any terms imposed on her by her adversaries. At this time she summoned her men of science to her assistance, and the call was speedily answered. Berthollet and Monge were particularly active, and saved the French nation from destruction, by their activity, intelligence, and zeal. Berthollet traversed France from one extremity to the other, pointed out the mode of extracting saltpetre from her soil, and of purifying it. Saltpetre works were instantly established in every part of France, and gunpowder made of it in prodigious quantity, and with incredible activity." "This famous instance," says the eloquent Fourcroy, "never will be lost."

At the present time, in Sweden, each landed proprietor is obliged to furnish to the state a certain quantity of nitre.

The principles of the method of forming nitre will perhaps be readily understood by the following abstract of the processes that have been followed. Decomposing animal and vegetable matters, mixed with cinders, lime, or marl, are placed in heaps (called *nitre beds*) under cover, the mass being occasionally moved, or holes made in it, so that they are exposed to the air. From time to time they are watered with urine (a liquid containing more nitrogen than any other animal substance.) At the end of two or three years the nitrogen has combined with oxygen, and this with bases to form nitrates. By lixiviation the salts may be separated, and any nitrate of lime present may be converted into nitrate of potash by adding wood ashes, which contain carbonate of potash.

At Appenzel, a canton of Switzerland, nitre is formed from the urine of animals. A hole is dug near to stables, and in this is put a sandy kind of earth, which is kept moistened with the water running from

the stables. In two or three years this earth yields nitre.

Preparation of rough nitre.—The saltpetre, or nitre, used in this country, is brought from the East Indies, under the name of *rough* or *grough saltpetre*. It is there procured by lixiviating the soils known to yield it.

Impurities.—In the rough state nitre has a yellowish colour, from some extractive matter, and contains several other impurities, principally the alkaline chlorides; these are designated in commerce by the word "*refraction.*" Thus if a rough nitre should contain ten per cent. of impurities, it is said to have *ten per cent. refraction.* How this term came into use in this sense, I know not

There are three modes of ascertaining the degree of purity of rough nitre: *one* is by dissolving and crystallizing the nitre; the *second* is by washing the rough nitre with a saturated solution of the pure nitrate, so as to remove the impurities, the quantity of which would be known by the loss of weight which the nitre undergoes; and the *third* is that proposed by Gay-Lussac, namely, converting the nitrate into carbonate, by calcining it with charcoal, and then determining by an acid the quantity of potash present. All these methods are more or less objectionable, the third being the least so; but the two first are those usually followed.

Purification.—Nitre is purified by repeated crystallization. When it has been only once dissolved and crystallized, it is called *singly refined nitre*; when twice, *doubly refined.* Its purity is to be ascertained by testing it with nitrate of silver, which ought to occasion no precipitate with it.

Properties.—When pure it is colourless, has a sharp cooling taste, is crystallizable, the primary form of its crystal being a right rhombic prism: it undergoes no change by exposure to the air. When heated it fuses; and if cast in moulds forms the *nitrum tabulatum*, or *sal prunelle* of the shops. At a strong red heat it is decomposed, with the evolution of oxygen and the formation of hyponitrite of potash. One hundred parts of water at 32° dissolve 13·32 of this salt, but alcohol dissolves much less of it.

Composition.—It is an anhydrous salt, composed of—

1 nitric acid	54
1 potash	48
	102

Its formula is $\dot{K}\ \overset{\therefore}{N}$.

Characteristic tests.—It is easily recognized to be a potash salt by the tests already mentioned for these salts. That it is a nitrate is shewn by its deflagrating when thrown on red-hot charcoal; when heated with sulphuric acid, it yields brown fumes of nitrous acid; if a little of it be heated with a few drops of sulphuric acid in a tube, and a crystal of morphia dropped in, the presence of nitric acid may be determined by the red colour observed around the crystal.

Physiological effects.—In very large doses (such, for example, as one ounce or more) nitre has in several instances caused death; but the effects of it are not uniform, since in other cases it has not appeared to have any very remarkable or obvious effect. For example, Dr Christison knew one ounce taken without occasioning any other unpleasant symptoms than vomiting; and it was retained on the stomach for above a quarter of an hour. In those cases where violent effects followed the ingestion of it, the symptoms were twofold: on the one hand those indicating inflammation of the alimentary canal (such as pain, vomiting, and purging); on the other hand, an affection of the nervous system (marked by giddiness, convulsions, dilated pupil, insensibility, and palsy.)

The effects of nitre in moderate doses are not well ascertained. It is said to act as a refrigerant; but it can only do this when the body is preternaturally hot, for Mr. Alexander, in his experiments, found no perceptible diminution of heat in the external parts of his body. It would appear, however, that nitre powerfully affects the vascular system, for in most of Mr. Alexander's experiments he found the frequency of his pulse diminished; and that this effect was in part owing to the nitre, and not solely to the cold water taken with it, seems probable from the diminished action of the heart observed in other cases. Thus in two cases of poisoning by nitre, quoted in Dr. Christison's work, the pulse failed at the wrist, and there was great tendency to fainting. Diuresis is another effect produced by nitre: this has been very generally observed, and the urinary secretion has been found to yield evidence of its containing this salt. The simplest way of proving this is by immersing a slip of paper in this secretion, and when dry it will be found to act as touch-paper. When taken in repeated doses, it has a slight tendency to promote alvine evacuations.

Uses.—Nitre is rarely employed as an external agent, except as a means of producing cold. Thus five ounces of nitrate of potash, with five ounces of muriate of ammonia, and dissolved in sixteen ounces of water, will reduce the temperature of the liquid 40°; that is, from 50° to 10°,

according to Mr. Walker. Hence, therefore, we sometimes employ this mixture, placed in a bladder, as an external application, as already mentioned in the last lecture. Internally it is frequently exhibited as a refrigerant in febrile disorders, hæmorrhages, and other diseases in which we wish to reduce the action of the vascular system. In sore throat it may be dissolved gradually in the mouth. As a diuretic in dropsical cases, it may be occasionally serviceable. A mixture of nitre and powdered gum-arabic was at one time a favourite remedy to diminish the scalding in gonorrhœa.

Administration.—It may be given in doses of from ten grains to half a drachm. If administered as a refrigerant, it should be dissolved in water and immediately swallowed, in order that the coldness of the solution may assist the action of the salt. If employed as a diuretic, we ought to give liquids plentifully, and keep the skin cool.

Antidote.—No chemical antidote is known for this salt; we must therefore, as quickly as possible, remove the poison from the stomach, and administer tepid emollient drinks.

REPORT

OF

A TRIAL FOR INFANTICIDE *.

By Charles A. Lee, M.D.
New York.

Margaret Crosslan, an unmarried coloured girl, aged 22, was indicted for murdering her infant illegitimate child, and concealing its death, on the 17th of Nov. 1834. Her trial came on during the second week in September, before the Supreme Court of Massachusetts, holden at Lenox, Chief Justice Shaw presiding, assisted by Samuel Putnam and S. L. Wilde, Esqs., Puisne Judges.

The following is the substance of the testimony taken by the coroner, Robert Waterman, 18th Nov. 1834.

E. Barker, sworn.— Abigail Crosslan has had every appearance of being pregnant for some months past, but last evening I informed my wife that something more than common was the matter with Abigail, and that I did not believe she would go longer than to-night or to-morrow night. Last night she appeared to be unwell, but denied that she was sick. This morning she went about her usual work, doing the chores, and was out for a considerable time. We went this morning for her mother. She came, and went up stairs to examine the bed where her daughter slept; she came down and told her that she had lost her child. At first she denied, and then confessed it, and said it was no bigger than her fist. We then went out to the barn-yard; we there found the after-birth, and a quantity of blood in several places on the ground. The child was soon discovered, and, after I had examined it, I went and informed E. Enrign, Esq.

Mrs. Barker testified, that she had accused Abigail of being pregnant; that she denied it; that on Monday, the day the child was born, she kept about her work as usual, went at night to the barn-yard to milk; that she was gone a little longer than usual; came in and went down cellar after candles; that soon after the witness saw something on the floor, which she called Abigail to mop up, asking her what it was? She replied she did not know. It was afterwards discovered to be blood. The next morning she got up and went about her usual work. Suspecting that she had lost her child, she charged her with it, but Abigail denied it. After some time, she owned it, but said it was no bigger than her fist, and that she had buried it with a stick in the barn-yard. On searching, the child was found behind and partly under the barn, wrapped in a piece of an old bag.

Drs. Oliver, Peck, and Silas R. Kellogg, examined the body, under the direction of the inquest. Owing to the circumstances under which the examination was made, it was not so thorough as ought to be made in such cases. The body was that of a full-grown male child, and no external marks of violence appeared, excepting signs of effused fluid under the scalp covering the frontal bones. Blood was found in considerable quantity, partly fluid, and partly coagulated. The pericranium was separated from the bone; the parietal bones were both fractured, the left one in three places, radiating from a central point; the right in one, being a continuation, apparently, of the middle fracture of the left parietal, across the vertex.

The effused blood was principally over the back part of the parietal bones, and the upper portion of the occipital. The chest was externally arched, the lungs collapsed, and somewhat spongy. Dr. Peck testified, that the lungs filled the chest; that the injury was not inflicted after death, and that a blow sufficient to cause such injury would destroy life; that it must have been done after the delivery of the child, as the action of the uterus could

---

* From the American Journal of Medical Sciences for Feb. 1836. We regret being obliged, in consequence of the length of his interesting report, to omit the *remarks* of Dr. Lee, subjoined in the original.—Ed. Gaz.

not fracture the bones; and that the circumstances of the case warranted the belief that it was done by the mother. To the question, by the court, whether the mother might not accidentally have caused the death of the child, by grasping the head for the purpose of facilitating delivery, it was replied, that he thought not—it was indeed possible that the bones might be fractured in this way, but if produced in this manner, it would not probably cause so much extravasation of blood. He thought it very difficult for a woman to be delivered standing, though it was possible; that females in labour instinctively seek a situation where they may support themselves and be supported—that is, a reclining posture; that the probability of the child's being born while the mother was standing, was increased in this case, by the circumstance that the labour was short, and that it occurred in a barn-yard; that, therefore, it was possible that the death of the child was occasioned by its falling on its head, upon the frozen ground.

Dr. Kellogg testified to nearly the same effect; he thought, however, that the fractures could hardly have been caused by the mother's grasping the head of the child, as the bones before the union of the sutures would lap upon pressure. At the time the inquest was held, he formed an opinion that it came to its death by a blow inflicted by a stick or some hard substance. In examining the lungs, a portion only was cut off from each, an inch and a half or so in diameter. In the first experiment, the temperature of the water was about 80 degrees of Fahrenheit; in the next it was of the ordinary temperature of the atmosphere. The lung floated readily in each; the pieces remained in the water three or four minutes. The whole lung was not removed, as they were pressed for time. Did not observe any appearances of blood in the lungs, and did not try whether they would crepitate on pressure. A child may be said to be born alive, when it is furnished with such an organization as to be capable of maintaining an independent existence, when separated from the mother. Could not say that this child was born alive in this sense—thought a woman would naturally, and, under all circumstances, seek a reclining position in labour—the effusion of blood might have been caused by a blow given shortly after death—thought that the presence of arterial blood in the lungs would furnish a much stronger proof of the child's having breathed than extravasated blood under the scalp.

Dr. C. A. Lee, on behalf of the prisoner, testified that he believed there was no difficulty in a woman's being delivered standing; that he had delivered several in this posture; had often known females seek such a position, resting their hands or arms on a chair placed before them; thought it a very natural and easy position for a strong lusty woman; that some of the older works on midwifery directed women to be delivered supported on crutches; had known cases where parturition had been effected by a single pain, and so suddenly that the mother had no time to get into a bed, or in a reclining position; that if a woman was suddenly seized with such violent labour pains in the street, or in a situation where the usual conveniences were not to be had, it was most probable she would be delivered standing; that this was probably the fact in the present case, as the fractures were in the very place we should expect to find them, had they resulted from such accident.

Dr. Sellor, of Amherst, also testified to that effect; and Mr. Swan, that his own wife was delivered in the same way. On the cross-examination, the medical witnesses for the government testified, that, in such cases, the physician ought to proceed according to the best authorities. The heart should be taken out with the lungs; the large vessels tied; the ductus arteriosus and venosus examined; also, the foramen ovale, the brain, and abdominal viscera; and, particularly, the colour of the lungs, crepitous feel, &c. All the tests should be used in such cases which are recommended by writers on the subject, and even then there will remain a sufficient degree of uncertainty.

On summing up the case, H. W. Bishop, Esq., on the part of the prisoner, after a happy exordium, in which he adverted to the importance of the case, remarked in substance, that he should confine his observations chiefly to the first count of the indictment, which charged Margaret Crosslan with destroying her infant child; the government here were bound to make out a clear case—they must not talk of probabilities or of circumstantial evidence, the burden of proof rests upon them. As to her pregnancy, that we are willing to concede, but they must prove that this child was born alive, and with organs sufficiently perfect as to support life independently of its mother.

Was this child born alive? The physicians, able and learned as they are, and distinguished in their profession, are still young, and they had not the means at hand of conducting the examination according to the most approved tests. It is very evident that it was not satisfactory to the physicians themselves; and how was it conducted? The books direct that extreme caution should be used in such an

investigation. 1st. The general appearance of the body is to be carefully noted, its size, weight, and strength, as also the proportion of the different parts carefully ascertained, whether there are signs of putrefaction, desquamation of the cuticle, ecchymoses, and other marks of violence, and particularly whether the umbilical cord has been ruptured or cut; and if ruptured, whether at the end or in the middle. If there are effusions of blood about the head, it is to be inquired whether it is probable they were produced by efforts of parturition, or by external violence. It should also be ascertained whether there are any foreign bodies in the mouth or trachea. These and many other particulars are to be ascertained, before proceeding to the dissection, which ought to be pursued in the manner recommended by Beck, Smith, and other writers on medical jurisprudence.

After laying open the cavity of the chest, it should be observed whether the lungs fill the thoracic cavity, or whether they are shrivelled and collapsed, and particularly whether their colour be florid or lightish gray. The position of the diaphragm should then be noticed, whether it be depressed or elevated. The ductus arteriosus and foramen ovale should also be examined, to ascertain whether they are open or closed.

The large vessels are now to be tied, and the heart and lungs taken out together, in order to subject them, in a satisfactory manner, to the hydrostatic test. In this experiment the temperature of the water should be that of the atmosphere, and care should be taken that it contain no gall. After using these precautions, and ascertaining whether the lungs will float, with the heart attached, the large vessels are to be tied, and the heart separated; after trying whether they will then float, they are to be weighed, in order to ascertain their relative weight compared with that of the body. This constitutes what is called the test of Plouquet; it is not the most valuable, but it is one which writers say should not be omitted. Incisions should then be made into the lungs, to see whether the tissue be spongy or compact, healthy or diseased, colourless or florid, whether crepitous on pressure, and the blood-vessels injected. These are only a few of the particulars to which the attention of the physician must be directed, in order to form any satisfactory opinion whether the child respired after birth. In the present case these points were nearly all omitted; nothing was done but to cut off a portion of each lung and throw it into warm water — of course it would swim; the temperature of the water would cause such a rarefaction of the fluids and the air vesicles as to sustain it upon the surface, even though the infant had never breathed. The experiment is, therefore, wholly unsatisfactory. True philosophy is not satisfied with a single experiment. She refutes and changes them in every possible manner, before she deduces those general principles which she is willing to publish to the world. The condition of the pulmonary blood-vessels has always been considered a most important indication in such cases. If they are found charged with arterial blood, the surface of the lung presenting red points when cut into, it is very conclusive proof that the child was born alive; and we have the testimony of the physicians, that this would be a far better test than the extravasations of blood which were found about the head. Yet even this point was neglected in the hurry of the examination.

Again, we are told that there were fractures of the parietal bones, and considerable effusion of blood under the scalp. This being partly fluid and partly coagulated, is supposed to prove that the circulation was going on at the time the injury was received. Yet such appearances have been found where the infant did not survive delivery, and from the contractile force of the uterine pains. Physiologists tell us that the moment the nervous agency was destroyed the circulation ceases, as in cases of death by lightning, and severe blows, &c. If a blow, however, is received sufficient to impair, but not entirely destroy the nervous power, the circulation will go on as usual, as long as life continues. Such extravasations may, moreover, be caused by fœtal circulation, without supposing that the child ever breathed. It rests with the government to prove, that this infant was born alive, and capable of supporting an independent existence; *i.e.* that its nervous, sanguineous, and circulatory systems, were sufficiently perfect. Has this been done? But if the child was born alive in this sense, who killed it? Was it destroyed by exposure to cold, falling upon the frozen ground, by a blow from the mother, or by her dashing it to the earth? The government say, it was by one of these particular modes; let them prove it. I know that it is possible the infant might have lost its life by blows inflicted by the mother, but we are not now called on to discuss possibilities, or even probabilities; the government must show that violence has been committed.

As to cases of delivery, when the mother is standing, they may be rare, but they do sometimes happen, as the medical witnesses for the prisoner testify. They may not often occur in genteel practice, and the reason is, that labour is usually more protracted, and the female is directed by

her physician to take a reclining position; but in humble life it is far different. Now, gentlemen, this poor, ignorant girl, was delivered on the night of the 17th of November, on frozen ground, in a barn-yard, during a storm of commingled rain and sleet. It is worthy of remark, that there were no marks upon her clothes, as there must have been had she lain down, and thus been delivered. This is strong evidence that she was delivered standing. The cause of the fractures on the top of the skull will now be obvious: they were caused by the child's falling suddenly to the frozen ground. In Beck's Medical Jurisprudence, we have an account of a series of experiments performed in a French Hospital, to ascertain from what height a fall upon the head of a still born infant would fracture the skull. In a large majority of cases it was found that a fall from the height of eighteen inches, was sufficient to break the parietal bones; and what is worthy of particular remark, is, that the fractures in these experiments were caused in precisely the same situation in which they were found in the present case. It is then shown that a slight blow, comparatively, will fracture the cranium of a new-born infant. It has been proved that the manure had all been removed from the yard a day or two previous, and that the gravelly soil, rendered compact by long treading, was moreover frozen, thus presenting a surface as hard as the walk before this court-house. But the prisoner is charged with being "wilfully delivered in secret;" but she was not so delivered. It was her wish that it might happen under different circumstances; but imperious necessity forbade. You may be told that she might have gone to the poor-house; but this supposes a knowledge of the law. She could neither read nor write, and knew nothing about the poor-house; she knew that Mr. B. would not have her in his house; she had no home at her drunken father's; and no place to which she could go and find a comfortable asylum.

The conclusion of Mr. Bishop's able argument was occupied in showing that there were sufficient motives for the prisoner's concealing the child, without supposing that she destroyed it and then concealed it, for the purpose of secreting its death.

On the part of the commonwealth, Mr. Austin, the Attorney General, remarked in substance, that he was not about to make a formal speech, but to reason with the jury, and converse with them, as rational men, anxious to come at the truth, whatever it might be. Laws like this, which punish capitally for taking the life of a human being, are of the mildest kind. They tend to the preservation, and not the destruction, of life. But it is better to have no laws, than such as cannot be executed. Now, if the doctrine, for which the opposite counsel contend, be true, then it can never be shown in any case that a woman is guilty of infanticide. No direct evidence is to be expected in a case of this kind; for it pre-supposes that it is done secretly, and we have to rely on circumstantial evidence alone. As a general rule, no direct proof can be furnished; and if such is to be required, then all this legal array is a mere mockery, and you have been called from your homes and firesides for nothing. All you can ask, is, the *best evidence of the kind*. And now, what is the case? It is, that a wanton and lascivious woman was in a condition to have a bastard child, as she had already had one; and she knew very near, if not exactly, the time when she might expect her accouchement. In the next place she denied her pregnancy—made no provision for the infant, and no attempt to find a suitable place in which she might be delivered. In this situation, when the time came, she went into the barn-yard, was delivered by a rapid process of labour, destroyed the child by blows upon its head; wrapped it in an old cloth, hid it under the barn; then returned to the house, said nothing about what had happened, and when charged with losing her child the next morning, she denied it—at length confessed it, but said it was no larger than her fist, and that she had buried it with a stick. Now, all these are circumstances furnishing strong presumptive evidence of guilt, and you are to give them their full weight in forming your verdict. If there is not satisfactory proof that the child was born alive, then the prisoner is to be acquitted; or if born alive, and accidentally fell from her arms, or propelled by the efforts of labour to the earth, then she is not to be declared guilty. Now, it is possible that the child came to its death accidentally, or that the mother destroyed it: you are to decide which. There is nothing, scarcely, but what may be said to be possible. It is absurd to talk of reasonable doubts, when all the evidence is adduced which ought to be expected. As the child was not heard to cry, the opposite counsel tell you we have not the best evidence of life. But there is far better evidence of life than that; walking is better, and talking is better still. But, supposing that the child had cried, it could only have been heard by the mother. But was the child born alive? The opposite counsel have brought a French book here, which I think had better have remained in France, in which the opinion is maintained that a child may breathe, and

still not be born alive. It may be technically true, that an infant may be born with such an imperfect organization as not to be able to maintain an independent existence, and thus speedily perish, but such a case would exhibit no marks of violence. But it is contended that a child may be half born and breathe; but from pressure on the cord, or other causes, may be still-born. The law knows nor recognises no intermediate stage. This is a horrid doctrine, and, if established, must lead to horrid consequences. If no other good results from the present trial than to place a veto upon such a doctrine, it will prove a lasting benefit. You are to inquire whether there is satisfactory proof that this child breathed, and whether it had the capacity of maintaining life. Here science comes to your aid, and philosophy stretches forth her helping hand. There are eight or ten different modes of ascertaining whether an infant was born alive. Can you expect that physicians will try all their tests, and keep a coroner's jury all night to go through them all? No! They will take this course:—they will try a sufficient number of experiments to make up an opinion; if not satisfied with one, they will proceed to others. Complete satisfaction is all you ought to ask. A cask cannot be more than full. Now, there are two grand tests: one is called the hydrostatic—the other, the test of Plouquet. After the child has breathed, the lungs become specifically lighter than water; before respiration, they are heavier, and sink. If, then, the lungs be immersed in water, and float, we infer that the child was born alive; and this was the fact in the present case, as proved by the medical witnesses. If the experiment was a fair one, and satisfactory to the physicians, what more do you want? One such experiment is as good as a thousand. But it is objected that warm water was used, and therefore no dependence is to be placed upon the test. There would be some foundation for such an objection, had the temperature of the water been as high as 200°, but the doctor testifies that it was only about 100°, and 80° is said in the books to be the most suitable temperature. It should be recollected, moreover, that the lungs floated in cold water likewise. Now, there may be, and are, exceptions to all rules; and so it is here. Putrefaction or artificial inflation may both cause the lungs to float, but neither of these are contended for.

The test of Plouquet consists in ascertaining the relative weight of the lungs, compared with that of the body, as that of the lungs is increased after the circulation of the blood through them has taken place by the establishment of respiration. But this experiment requires very nicely adjusted scales and the greatest care, and it is one which, in ordinary cases, cannot be performed. To the objection that a child may breathe when but half born, and then die in this amphibious state, before it is wholly brought into the world, it is hardly necessary to reply, by showing that this could not have taken place in the present case, as it only happens in tedious and protracted cases; and, besides, in such instances the skull surely could not have been fractured, without culpable negligence or manifest design on the part of the mother. Was there a sufficient motive for her to take the life of this infant? There was. It was to get rid of trouble, shame, and suffering. She had already been disgraced by giving birth to a bastard child; she was afraid to be confined at Mr. Barker's; she could not go home to her father's; and she thought if the child was only out of the way, she should get along easily. This was the motive, and it was a malicious one. The blows upon the head caused its death, as is known by the effusion of blood, which could not have occurred after death. The fact of the concealment of the child has again and again in our courts been decided as proof to show that the mother was guilty of the murder. In ordinary cases, if a person should die in company with another, would the latter attempt to conceal it? Would a woman hide her child under a barn if it happened to perish during delivery? Should she do so, would it not be a suspicious circumstance?—ought not some satisfactory reason be given for it? Had she not been guilty, would she not unhesitatingly have carried the child into Mr. Barker's, instead of denying its birth and its death? If there is a single point established in morals, it is that guilt and falsehood go together. Innocence never prompts a lie. There, then, is conclusive evidence that she was criminal. But it is objected that the child may have fallen to the ground, and thus fractured its skull and caused its death. Reference has been made to experiments performed in a French hospital, where still-born infants were suspended by the heels, and thus let fall head foremost upon a hard floor, fracturing their skulls. From these you are asked to draw the original inference, that an American woman may go into a barn-yard, stand up, and with one mighty throe give birth to a child; that that child may respire, have the blood sent through its lungs, and all the phenomena of life be fully developed in its passage from the mother to the ground! There is not a case on record where a woman voluntarily assumed a standing position to be delivered. Those French physicians

who performed these experiments do not say that women are ever delivered standing. Animals are guided by instinct to lie down when in labour, and woman also, in the extremity of pain, is prompted to take the same posture. But it is contended that this infant breathed, and then was propelled by another pain to the earth. If so, this must have been a very remarkable birth. It had to fall but eighteen inches, and if it stopped short half way to breathe, it could not have fallen even thus far, and certainly not sufficiently rapidly to cause its death. Besides, how are you to account for the extravasation of arterial blood? (Here Judge Shaw observed, that the physicians only testified that the extravasation, in their opinion, showed the existence of fœtal life at the time of the accident, and not that respiration was established.) After some further remarks on this point, Mr. Anstin concluded his argument, by saying, that the case derived much of its importance from the probability of its being quoted as a precedent, and as influencing future decisions. After an able review of the testimony, by Judge Shaw, the Jury retired, and the next morning brought in a verdict of *Not Guilty*.

[In his remarks appended to this Report, Dr. Lee comes to the conclusion, that the verdict was a correct one; and that the child, "if born alive, came to its end by accidentally falling on its head."

The arguments of the learned counsel, we beg leave to add, do them the highest credit. We wish *our* barristers were prepared to grapple with questions of this kind with the same ability and extent of medico-legal knowledge.—Ed. Gaz.]

CASE OF RECTO-VAGINAL FISTULA SUCCESSFULLY TREATED.

To the Editor of the Medical Gazette.

Sir,

If you think the enclosed case, copied from my note-book, sufficiently interesting, I will thank you to give it a place in your valuable publication.

I am, sir,
Yours truly,
George Fielding.

Hull, March 22, 1836.

On the 4th of December, 1834, Mrs. D. ætat. 29, a tall, healthy, fine-looking woman, reports—that on 22d March, 1833, she was delivered, by instruments, of a dead child, after a hard labour of three days,—that on the second day she was very feverish, suffered great pain, and passed no urine until the afternoon of the 23d, by catheter, which was employed eighteen days; the bowels were opened that day with considerable pain and difficulty, and the nurse distinguished something like a shred of dead matter hanging about the parts. She again took opening medicine on the 27th, when she found, to her very great distress, that she had lost all power of retention, and the fæculent matters passed from her involuntarily as she lay in bed. In time, the soreness and pain subsided, the bladder recovered it's tone, and she regained health and strength; but from the 27th to the present hour she has never been able to retain the alvine contents, (except now and then when very costive) which passed off at all times and in all positions.

Many remedies had been proposed and tried; amongst others, sponges and pessaries, without success. On examination, I found no vestige of perinæum: a cicatrix extending from the commissure of the labia downwards, along the inner side of each tuber ischii, was apparently lost in the anus. Upon dilating the parts fully, a semilunar aperture at the posterior part of the vagina was discovered, more than half an inch in depth, and of nearly the same breadth; the finger passed at once through this opening into the rectum; the posterior and lateral parts of the rectum seemed to be entire. This semilunar aperture was found to involve a part of the posterior wall of the vagina, a portion of the anterior part of the rectum, and the sphincter connected with it.

Hence the inability to retain any matters in the cloaca, and hence it would appear that there had been a sloughing of the perinæum, posterior wall of the vagina, and the corresponding anterior portion of the rectum with the sphincter. Under such circumstances, little could be confidently promised; however, I proposed to try the following operation, with a view to restore, if possible, the use of the sphincter, so as to enable her to have some command over the fæces—a matter of great importance to one who appeared scrupulously neat and cleanly in her person and habits.

Dec. 10th.—After due preparation, I pared off the edges on both sides of the semilunar aperture from the involucra

of the sphincter upwards to a point at its apex, in the way usually practised in hare-lip; the incision then resembled the letter Λ inverted; the lips were now drawn carefully together by two sutures, one through the sphincter, and the other higher up; no dressing employed; the patient kept in a recumbent position, and dieted on barley water and tea. The only inconvenience that followed the operation, was pain in the direction of the coccyx up to the loins during that day and the following night, but without febrile symptoms; and retention of urine for nine days, for which the catheter was employed.

13th.—The threads having become slack were carefully cut and drawn away; there was partial union at one part of the sphincter, with healthy granulations above and below it.

16th.—Granulations slightly touched with arg. nitr.; and on the following days.

17th. — Nothing having passed the bowels since the operation, a little castor oil ordered.

18th.—A liquid alvine evacuation; does not think herself any better, but it is clear that granulations are filling up the aperture more and more; an extra sized wax bougie passed two or three inches up the rectum every day, and retained a short time; same diet observed; allowed to sit up a while.

21st. — Castor oil again taken, the bowels not acting.

22d.—This morning, as soon as I made my appearance, with every expression of delight in her countenance, she said, " Sir, I have the pleasure to tell you, that when the oil operated this morning, I had sufficient command over myself to pass from this room up one flight of stairs without any inconvenience, the first time since my confinement" (twenty months). The parts filling up and closing; same treatment pursued; a little better diet.

25th.—Bowels have acted naturally once a day; has no difficulty of retention until she can retire; the parts now present only an irregular line, in place of the deep aperture; granulations not entirely healed; took an airing in a carriage.

Jan. 24th, 1835.—Have seen Mrs. D. twice since last report, and touched the parts with caustic, which are now quite healed. Instead of the deep indentation, they present only an irregular line. Mrs. D. informs me, that she has ever since the 22d. ult. had perfect command, even when obliged to take aperients.

Jan. 1836. — Since the above was written, Mrs. D. has given birth to a living child, and remains well.

PHYSIOLOGY AND PATHOLOGY OF THE ANIMAL FLUIDS;

CONTAINING

Experiments and Observations on the Effects of Certain Substances upon the Blood; on the Coagulation of the Blood; on the Difference between Membranous and Sanguineous Serum; on the Formation of the Buffy or Inflammatory Crust; on the Formation of Pus; on the Functions of the Lymphatic System; and on the Process of Sanguification.

By Andrew Buchanan, M.D.,
Junior Surgeon to the Glasgow Royal Infirmary.

The numerous subjects comprehended in the preceding title may appear heterogeneous enough, but I hope to be able to make it appear that there is a link of connexion existing among them. Considered under a medical point of view, they all relate to the changes which the albuminous fluid named serum is liable to undergo from the action of the bodily organs, or from the re-action of its own elements; and considered under a physiological point of view, most of them are more or less connected with the complicated process of sanguification.

Some of the experiments which I am about to detail, were made as far back as the year 1820, when I was resident in the Royal Infirmary of this city, and had plenty of blood in the liquid state at my command. Most of them, however, were made in the winter of 1830-1, when I enjoyed equal facilities in conducting them, from holding the office of surgeon to one of the six districts into which at that time the town was divided. I continued to prosecute these experiments as opportunities presented themselves in my private practice, or were afforded to me by the kindness of my medical friends. I have had many opportunities of repeating and confirming them since I commenced acting as attending surgeon to the Infirmary, in the beginning of last summer, but I have not been able to add to them any new fact of importance. The experiments on the formation of pus

bear the earliest of these dates. The experiments upon the blood then made, were undertaken with the view of establishing that the substance named *fibrin*, which constitutes the basis of the clot of blood, was merely a modification of serum, and not entitled to be considered as a distinct animal principle. That conclusion, although not warranted by the experiments then made, is abundantly established by subsequent experiments, which shew that the basis of the clot is formed by the combination of sanguineous and membranous serum. The experiments made in 1830-1, were undertaken for an object which had no connexion with the results to which they led. In the prosecution of an inquiry into the action of medicinal agents upon the human body, I was led to mingle various substances with blood in the liquid state, as it flowed from the arm. I tried in this way various simple substances—alkalies, acids, salts, and metallic preparations; but these experiments I pass over, as having no connexion with our present subject. I next tried substances of an organic kind. The results afforded by some of these last experiments were not less interesting than they were unexpected; and it is to them that I have now to request the reader's attention.

1. *Membranous serum, and liquified coagulum.*—Without regarding the order of time in which these experiments were made, I pass over those made with sweet oil, and with gelatin, and shall first mention those made with serum from the tunica vaginalis testis.

On the 20th of March, 1831, I tapped a stout healthy young man for hydrocele. There was drawn off more than a pint of serum, which was clear straw-coloured, and very rich in albumen. I had previously ascertained that the crassamentum, or clot of blood, admitted of being completely broken down, and again reduced to the liquid state, by expression through a linen cloth. Having treated in this way the crassamentum of some blood drawn the day before, I mixed the liquified crassamentum with a portion of the hydrocele serum. Next day I found that they had formed a coagulum together. The coagulum was of a perfectly homogeneous structure throughout, firm, florid, and translucent; no serum separated from it, as from the common coagulum of blood. On repeating this experiment, I always obtained nearly the same result. The colour of the new coagulum was more or less pale, according to the quantity of red particles which it contained. The coagulation took place even when the liquified crassamentum was considerably diluted with water; in which case the coagulum obtained so exactly resembled red currant jelly, that it would readily have been taken for that substance, but for a knowledge of the mode in which it had been prepared.

To ascertain whether the secondary coagulation did not depend upon a property which the disintegrated clot might possess, of coagulating spontaneously, I reduced a clot of blood to the liquid state by expression, and allowed it to stand 48 hours. No coagulation took place, nor did the liquid in any respect alter its appearance, except by becoming a little thicker from spontaneous evaporation. On now adding a portion of serotal serum, the secondary coagulation took place as usual. The liquified crassamentum has, therefore, no tendency to re-coagulate *per se*, the secondary coagulation being obviously owing to the addition of the serotal serum. I found, in like manner, that the secondary coagulum, on being broken down into a liquid, did not re-coagulate spontaneously.

I next tried whether the liquified crassamentum would re-coagulate on mixing it with the serum of the blood, but no coagulation ensued, shewing a difference of properties in this respect to exist between the serum of the blood, and the serum I had derived from the serotal cavity.

My next object was to ascertain whether the property which I had recognized in the serum, upon which my experiments had been made, depended on any accidental circumstance, or was a general property of the serum exhaled into the serous cavities. The first experiments for this purpose were made with serum obtained from the abdomen of a female who died of ascites, consequent upon a scirrhous state of the stomach. I had twice tapped the patient, once in the usual way, and once through the urinary bladder. She died after a very protracted illness, in a state of great emaciation. Notwithstanding, the serum found in the abdomen after death was not deficient in albumen, and on trying it in numerous experiments with liquified crassamentum, I found it to comport itself, in every respect, like the

serum from the tunica vaginalis testis. The coagulum formed, became florid, or arterialized on the surface, where it was exposed to the air, and, as in the previous experiments, there was no separation of serum. Some time after, I had an opportunity of repeating these experiments with serum obtained from the cavity of the chest; and obtaining the same results, I then considered myself entitled to conclude that the property of forming a new coagulum with the liquified crassamentum of blood, was a general property of the serum exhaled into the serous cavities. It will be seen, however, below, that this general rule is not without its exceptions.

2. *Membranous and sanguineous serum.*—From the experiments I have related, I was disposed to conclude that it was the colouring matter of the blood which gave to the liquid mass its tendency to coagulate, and a considerable period elapsed before I discovered the fallacy of that opinion. The following experiments had the effect of undeceiving me in this matter. I mingled together some peritoneal serum, and serum of the blood; a coagulum was formed, but not a complete one, a portion of the mixture remaining liquid. I repeated the experiment, but it did not succeed. I was uncertain whether to impute the failure of this latter experiment to the change of qualities in the peritoneal serum, which was now so far advanced in putrefaction as to smell most offensively, or to suppose that in the first-mentioned experiment, I had been deceived by the presence of colouring matter in the sanguineous serum, which often contains more or less of it. To remove this difficulty, I procured ℥x. of a light straw-coloured serum from the body of a man who died of an abdominal disease, but who had also a hydrocele, from which I drew off the water after death. With this new supply, I repeated the experiment of mixing together membranous and sanguineous serum. To prevent any admixture of colouring matter in the sanguineous serum, I drew it off from around the clot of blood by means of a syringe, and thus obtained it perfectly limpid. About equal parts of the two kinds of serum were mixed. A beautiful pellucid and pretty firm coagulum was formed. It was sufficiently firm to admit of being transferred from one vessel to another, without breaking. It was, when first observed, of the same volume as the liquid in which it was formed, but gradually contracted in size. I have since repeated this experiment very frequently with serum obtained from the serous cavity of the testis, from the cavity of the peritoneum, from the cavities of the pleura, and from the pericardium. The result has generally been the same as I have just described, but not always so, as will be seen in the account of some experiments inserted below. With serum, again, obtained from the serous cavities of the head, and from the cellular membrane, the success of the experiment has never been but imperfect.

I was thus satisfied that the colouring matter of the blood had no share in producing the coagulation observed in these experiments. To show this more directly, several experiments were made by mingling membranous serum with the colouring matter of the blood, separated from the clot by means of water, but however strong the solution, no coagulation was produced.

The best mode of observing the coagulum formed by membranous and sanguineous serum, consists in mingling equal parts of the two liquids in a watch-glass, or larger vessel of a similar shape, and viewing them from time to time, by placing the glass vessel in a favourable position, between the eye, and the light of a candle. In this way the coagulation may be perceived before the coagulum has acquired sufficient solidity to be easily seen in passing the serum from one vessel to another. It will be farther seen that the coagulation goes on increasing for several days. The structure of the coagulum also is best perceived by this mode of observation. The coagulum is obviously of a cellular structure. It has at first very much the appearance of a cobweb spun through the liquid; and although it afterwards becomes denser, it is still distinctly seen to consist of solid filaments, intersecting each other in all directions, and thus forming a net-work, in the meshes of which is contained that portion of the two serous fluids which retains its liquidity. This being exactly the texture of the common cellular membrane, it appears to me not improbable that a coagulum of this kind may be the matrix in which the cellular tissue is primarily developed. On pouring off the liquid surrounding the coagulum, and contained in its meshes, and substituting water for it, the coagulum contracts in

size, and assumes a membranous form. It is of a pure white colour, is insoluble in water, cold or hot, and possesses the other characters of fibrin. On putting the coagulum upon a linen cloth, the liquid filters through, leaving the membrane behind, which is sufficiently firm to admit of being rolled up, and again unrolled in water, without laceration. Altogether the coagulum may be very aptly compared to the colourless species of Medusa, or sea-nettle, a portion cut out of the solid part of which is colourless and transparent, consists of a cellular tissue containing a watery fluid, and when that watery fluid drains off, or evaporates, shrinks in every direction, and leaves only a membrane behind. The vitreous humour of the eye is a texture of the very same kind, consisting of a liquid contained in the cellular meshes of the hyaloid membrane. The white of egg also consists of an albuminous fluid contained in the cells of a membrane, which is, I think, very probably not *organized*, (if we are to understand by that term the product of vascular action) but formed by a physical action, analogous to that described above.

3. *Liquid blood and water.*—The following experiment was intended to shew that the structure of the common coagulum of blood did not differ from that just described, except in having a much greater density.

Half an ounce of blood was received as it flowed from a vein of the arm, in a small gallipot. The same quantity was also received in six other vessels, containing respectively of water the following quantities, ʒss., ʒi., ʒiss., ℥ii., ʒiiss., and ʒiii. After mixing thoroughly the blood with the water, the vessels were set aside. Coagulation took place in all of them. It was only in the first, containing the pure blood, that the serum separated colourless; in all the rest it had a red tinge. In the first vessel, also, the serum was fully more abundant in proportion to the entire quantity, than in any of the rest; and among the latter, the proportional quantity was not regular. In every instance the coagulum was at first equal in volume to the whole liquid, so that in the largest vessel it was obviously diffused over seven times its natural space. The subsequent contraction was much greater in the first cup than in any of the rest. By cautiously immersing in water the vessels containing the larger coagula, the red colour was gradually washed out, the coagulum still retaining its original shape, although contracted in size. The decoloration was the more easy, the more diluted the blood.

I would remark, with respect to this experiment, in the first place, that it is quite impossible to deprive of its colour the natural coagulum of blood, without breaking it down; only the surface is blanched, but the internal parts retain their original colour unchanged, the clot being apparently quite impermeable by water. Now, if the coagulum be broken down, it is converted into a liquid, which we have spoken of above, under the name of *the liquified coagulum*. Hence it is, that in obtaining fibrin from the blood in the ordinary way, the greater part of it runs off with the water, in the form of liquified coagulum, while only a few shreds are left behind. The easiest mode, therefore, of obtaining fibrin from the blood, is to dilute largely with water the blood as it flows from the arm, and after coagulation has taken place, to pour a stream of water cautiously over the coagulum, till it ceases to acquire a red tinge. I treated in this way a pint of blood, diluting it with six times its volume of water, and afterwards macerating for a fortnight, when the greater part of it remained behind, in the form of a filamentous mass, of an uniform pale flesh-colour.

My principal object, however, in detailing this experiment, was to remark, that the structure of the coagulum is rendered obvious by dilution, and that it is then seen to consist of filaments interlaced in all directions, so as to constitute a cellular tissue, such as that described above. It is in the cells of this tissue that the serum seems to be contained, when the coagulum is first formed, and afterwards, by the contraction of the filaments, it is forced out upon the surface of the coagulum. It is only in its greater density that the natural coagulum differs from those obtained by dilution, or by mixing together the membranous and sanguineous serum. In respect of structure, therefore, the latter may be considered as bearing to the natural coagulum the same relation that the cellular tissue bears to the membranes of the body, which have been shewn by Haller to consist essentially of a condensed cellular tissue.

I shall now relate some experiments

which were made previous to most of those already mentioned, but which I have postponed till now, because they appear to me to exhibit the same phenomena that are described above, but in a more complex form, and I preferred beginning with the most simple.

4. *Membranous serum, and liquid blood.*—I received some blood as it flowed from a vein in the arm, in a vessel containing a portion of the serum which I had just drawn off from a hydrocele. The blood became a little florid as it mingled with the serum, and when coagulation took place, nearly two-thirds of the coagulum consisted of buffy coat, as it is called, or inflammatory crust. In other words, the whole colouring matter of the blood was collected in the undermost third of the coagulum, while the two upper thirds contained no colouring matter. The line of separation between the pale and the red coagulum was perfectly well defined, as in cases where the buffy coat is observed as a symptom of disease. The pale coagulum had about the usual degree of firmness, but it had in colour less of the buffy tinge than is observed in inflammatory diseases. It had more of the colour of serum, and was not unlike the coating I have occasionally seen upon the coagulum of blood drawn in typhus fever. The vessel in which the blood was received being shallow, the whole depth of the coagulum was only about an inch. There was no inflammatory crust upon the rest of the blood drawn.

I have repeated this experiment frequently, and although it does not always succeed, it has, nevertheless, succeeded so often as to satisfy me that the formation of the pale coagulum, or buffy coat, does not depend on any accidental circumstances, but is really the effect of mingling membranaceous serum with liquid blood. The circumstances which cause this experiment to succeed in one case, and to fail in another, I have not been able to ascertain. I have seen the experiment succeed when the serum was far advanced in putrefaction; and I have seen the same serum produce the effect with the blood of one individual, and fail of producing it with the blood of another. I have seen membranous serum which did not coagulate when mixed with sanguineous serum, produce the buffy coat; and, on the other hand, I have seen membranous serum, which gave a coagulum with sanguineous serum, give no buffy coat with liquid blood. Most probably the success of the experiment depends upon certain conditions, both in the state of the serum, and in that of the blood. Several cases in which this experiment did not succeed, or only imperfectly, will be found below, under the head of miscellaneous experiments.

An experiment, which appears to me analogous to that last mentioned, consists in immersing in membranous serum a portion of the coagulum of blood, but without breaking it down. Upon standing, the coagulum becomes covered with a gelatinous crust, and from this point the colourless coagulum extends in filaments to the rest of the liquid.

5. *Oils and liquid blood.*—The first experiment which attracted my attention to the subject of this essay, consisted in mingling together oils and liquid blood. I received some blood as it flowed from the arm, in a cup containing some sweet oil. When the blood coagulated, I found that the upper part of the coagulum contained no red particles, or in other words, there was a buffy coat on the coagulum, while the rest of the blood drawn exhibited no such appearance. The same result was obtained when the oil was simply poured over the surface of the newly drawn blood. Oil of turpentine gave results exactly similar, but upon the whole, rather more striking. I was disposed to ascribe these results to the chemical action exerted by the oils upon the serum and colourless coagulum. I transcribe from my notes of these experiments, the following remark, although I have since seen reason to modify the opinion expressed in it. "These experiments probably indicate that the formation of the buffy coat in disease depends upon the blood containing some ingredient incapable of combining with the colouring matter, and which may possibly be of the nature of an oil."

6. *Miscellaneous experiments upon blood, serum, and other animal fluids.*

(These experiments being very numerous, and of a very miscellaneous character, the author does not think it necessary to publish them, more especially as most of them have little connexion with the argument which follows).

[To be continued.]

110, St. Vincent-street, Glasgow,
March, 1836.

CASE OF HYDROPHOBIA.

To the Editor of the Medical Gazette.

SIR,

HAVING lately witnessed a well marked case of hydrophobia, I beg leave to forward you the notes I took upon the occasion, and to enable you to record the fatal termination of another example of this *opprobrium medicorum*.

I am, sir,
Your obedient servant,
WILLIAM ENGLAND, M.D.

Wisbech, March 31, 1836.

February 29th.—Elizabeth Rollin, æt. 37, unmarried, an industrious woman keeping a small shop in the village of Emneth, of spare habit, and of vigorous mind, seven weeks since was bitten in the left arm and ankle by a dog supposed to be mad. The arm was a good deal lacerated; but the wound cicatrized in three weeks. The teeth of the dog penetrated in six places, near the outer and inner malleolus. The skin in one place was abraded to the breadth of a sixpence; the other five were contused wounds. The ankle was five weeks before it healed.

Mr. Robert Wales, surgeon, of this town, was sent for between 10 and 11 A.M. She then complained of having had shivering and uneasiness for two days; the last two nights were passed without sleep; difficult deglutition, particularly of liquids; severe spasms of the pharynx; pulse about 85, hurried: complains of thirst and dryness of mouth; oppressed respiration; no pain. Was ordered to take immediately—

Hydrarg. Submur. gr. x.; Ext. Belladonnæ, gr. iij.

At 1 P.M. I was requested to see her. The following were her symptoms:—Countenance expressive of great anxiety, or "malaise;" mental powers vigorous, though she is somewhat alarmed by having been bitten, and the imprudent observations of her neighbours. Skin hotter than natural; respiratory movements very irregular; sometimes as slow as fourteen inspirations in the minute. Complains of general chilliness. No pain of head, chest, or abdomen; much oppression, or weight, referred to the lower third of the sternum; has constant thirst; salivary secretion not increased in quantity; tongue milky-white, not furred; pulse 128; visible pulsation of the carotid arteries; is desirous of drinking, but is unable to swallow fluids, even common water. On attempting to drink, she is seized with violent spasms of the pharynx, followed by very loud sonorous expirations; is able to swallow a small quantity of sago, not very moist. On the extremities of her fingers being immersed in tepid water, the spasms of the pharynx came on in a more aggravated degree; her bowels have been constipated for two days.

On inspecting the left fore-arm, a cicatrix, not indurated, was discovered over the centre of the extensor muscles: this cicatrix was about $1\frac{1}{4}$ inch in length. The left ankle presented on the outer and inner side the cicatrices of six teeth-wounds, apparently all contused except one, where the skin had been lacerated: these cicatrices were hard and elevated.

Sumat Olei Crotonis, gtt. ij. 2dis horis.

10, P.M.—Spasms as before, on attempting to drink water; pulse about 82; bowels not relieved.

Repetatur Oleum Crotonis, omni semihora. Morphiæ, gr. ij 2dis horis.

To have the vapour and hot-air bath.

March 1st, 7 A.M.—Spasms of the pharynx increased in violence and duration; has passed a restless night, without sleep, and without being able to swallow but a little bread sopped in tea; bowels relieved three times; alvine evacuations dark; unable to lie down in bed, from fear of suffocation; pulse intermitting, alternately slow and very rapid; secretion of saliva more than natural; tongue of the same milky appearance. She is disposed to be cheerful and jocose during the absence of spasm, and feels hungry, without the capability of swallowing food. After a violent paroxysm, she complained of being choaked, and begged for water: on tepid water being offered, she seized the cup, but could not get it nearer her lips than two or three inches. She then asked for cold water, and making a violent effort to take it, succeeded in dashing a small quantity into her mouth, and thought she had swallowed a few drops. Respiration irregular, and much oppressed; pupils dilated; says she would be quite well if she could swallow; the warm bath not used, from the efforts she

made to resist it; during the night there has been a great mucous discharge from the nostrils: a most violent paroxysm of pharyngeal spasm came on, that lasted, with little intermission, during three quarters of an hour; it appeared to be brought on by the sudden descent of a large volume of smoke from the chimney into the apartment. Upon the cessation of this paroxysm, she was prevailed upon to be bled,—about sixteen ounces of blood were abstracted, when approaching syncope came on: the venesection seemed to afford some relief.

Repet. Oleum Crotonis et Morphia.

4 P.M.—Has not been able to take the pills of morphia; spasms much the same; pulse smaller and quicker; violent mania has come on. Is impressed with the idea that she would have been relieved if drawn through salt water; abused her medical attendants for not acquainting her with the nature of her disease, and continually exclaimed to be left to die alone. Would not allow any person to approach her; the opening of a door, or the movement of persons in the room producing a current of air, brings on the recurrence of spasms. Skin is become cold; pupils much dilated; excessive secretion of saliva keeps running from her mouth: the mucous discharge from nostrils continues. Frequently attempts to spit upon persons near her; has constant inclination to vomit. The spasmodic and maniacal symptoms increased in severity, with scarcely any intermission, and she continued sitting in a semi-recumbent posture till half past 7 P.M., when, during a paroxysm not more violent than many others, she became pulseless, fell back in a state of asphyxia, and expired.

Upon subsequent inquiry of her relatives, it was ascertained, that immediately after being bitten by the dog, the wound was washed with saltpetre and water, a neighbouring blacksmith had sewed it up, and, contrary to her wishes, she had been advised by her brother to drink a herb drink prepared by a village quack, and believed to be a certain preventive of rabies; of this potion she took a large bottle. A few days before the disease developed itself, her brother persuaded her to take some more of the drink; she laughed at the idea, said she was in good health, and refused to do so.

The dog which wounded the unfortunate woman subsequently bit two other dogs; one of them died perfectly rabid. Several sheep were also bitten on the neighbouring farms, and died with similar symptoms, in a modified degree.

The friends of Eliz. Rollin would not allow a post-mortem examination of her body.

ON THE

MOTIONS AND SOUNDS OF THE HEART;

CHIEFLY WITH REFERENCE TO SOME OF DR. COWAN'S VIEWS.

To the Editor of the Medical Gazette.

SIR,

IN no way can such a medical journal as that of which you are the able conductor, be so useful to the medical world, as by affording a ready and willing channel for the communication to the mass of the profession, of the result of experience in medicine, and experiment and observation in physiology. Your pages teem with the valuable labours of many men at the head of the different branches of medicine, and of no subject have you had a larger share than of the opinions and discussions upon the theory of the heart's action. Of the numerous varied and vague hypotheses advanced, the many have had but an ephemeral existence, and have been refuted or abandoned as soon as formed; but some are still left, opposite to each other as the poles, and yet each finding strenuous and able supporters amongst our professed physiologists.

My attention was directed to this subject, by some observations in last week's Gazette, by Dr. Cowan, of Bath; and I would, if not taking up too much space, say a few words in opposition to his views.

I know not any thing more indispensable in public writing, than that it should be intelligible to the understanding of those who are likely to peruse it: that by far the greater part of Dr. Cowan's observations are perfectly unintelligible to me, I must confess, and I would willingly ascribe it to my own dulness, rather than any want of perspicuity or consistency in Dr. C.'s relation, were it not that there are some parts that I will defy the most subtle of his readers to understand, or even himself to explain; as for instance, when, insisting upon the active elevation of

the mitral valves, he says, "The valves are, therefore, *muscularly tightened* from the first moment of ventricular contraction; they are every where raised from the muscular parietes, on which they passively repose during the systole, and their functions, &c."

But it will be more fair, and quite as easy, to combat his arguments, and to disprove his deductions, as to point out instances of verbosity or inconsistency, and I will proceed at once *ad argumentum.*

Dr. C. lays particular stress upon a fancied division of the left ventricle of the heart into two distinct portions, acting, as it seems, in some measure, independent of each other. I say fancied, because I cannot see the truth of this arbitrary arrangement; but even allowing that it does exist, it will not avail, for the only deduction that Dr. C. draws from it will not bear the test of a moment's scrutiny. He says, that upon the passage of the blood from the auricle, these two portions dilate successively, and that consequently there cannot be the conflicting currents and collisions of the particles of the fluid, ascribed by some as the cause of sound, but that the flow of blood, instead of being sudden, must take place "*gradually.*" Now, suppose that the heart acts sixty times in a minute, or once in a second, (far below the mark) and that two ounces of blood (the acknowledged quantity) are received and transmitted at each time, it is well known that the period of the action of the ventricle is in this ratio,—half the time for the contraction, one quarter for dilatation, and one quarter for repose. Thus two ounces of blood pass in a quarter of a second into the ventricle; and yet Dr. C. says that it is done "*gradually:*" and when we consider this fact, with the nature and size of the auriculo-ventricular opening, there will be no difficulty in allowing that there must be conflicting currents and collisions of the fluids.

Having, I think, shewn, that Dr. C.'s arguments, to prove Dr. Hope and others wrong, are not very valid, I will examine into the value of Dr. C.'s own opinion as to the cause of sound, in ascribing it to muscular contraction. He says, it is known that muscles do produce sound during their contraction; I do not know any such thing, nor do I believe it. I could never detect any sound produced by the most energetic action of the most powerful muscles, though I have often tried the experiment. I deny that any reliance can be placed on the opinion of the older writers, as instanced by Dr. C. The only one that would weigh with me would be Laennec. But Dr. C. takes him too literally; he did not mean that the sound was produced by the actual muscular action, but merely in general by the ventricular systole, and, in my opinion, he did not attempt to explain the immediate or proximate cause of the acoustic phenomenon.

Dr. C., in particularly directing attention "to the physical conformation of the cardiac cavities, as well as their valvular appendages,—and a strict association of these with the hydrostatic condition of the circulation," seems to have entirely lost sight of the valuable signs that are to be drawn from a consideration of pathology. I have heard it said, that no reliance can be placed on physiological deductions drawn from pathological evidence; but in many organs of the body, and especially in the heart, we can arrive at no correct conclusion without it. The heart, when diseased, is frequently materially altered in the extent of its cavities, and in the thickness of their muscular parietes. In concentric hypertrophy, *i. e.* with diminution of the cavity of the ventricle, and where the heart beats with twice the energy and power that it does in health, there is a remarkable diminution of the sound; now, if muscular action were the cause of the sound, when that action was increased in a very marked degree, there must be a proportionate increase of sound; but the very reverse is the case. When the cavity is increased in size, with such a distension of the walls that they cannot act very forcibly, according to Dr. Cowan's theory there should be a diminution of sound, because the energy or power of muscular action is lessened: but the very opposite is the fact, and the increase of the sound is in direct ratio with the increase of the cavity and attenuation of the walls, up to a certain point, when the phenomena are much altered; the cavity is enormous, the power slight, and the sound scarcely audible. This I can easily explain consistently with my own view of the case, for when the enlargement is excessive, the mitral valves cannot close, the ventricle can make but little effort to expel its contents, its action is

changed into a feeble vibrating, and the blood, instead of being forcibly compressed, is merely carried on by the *vis-a-tergo*, and pursues the even tenor of its way through the cavities of the heart, this organ acting as only an obstruction, and not as a powerful assistant or principal in the circulation. These are facts well known to pathologists, and, if true, must completely overturn the theory that Dr. C. advocates; for, if the sound be produced by the contraction of the muscular fibres, it must be augmented or lessened by the increase or diminution of that action; whereas, in fact, the very reverse is the case.

But, even supposing that the first sound could be produced by this action, to what could be ascribed the second sound? Not to the contraction of the auricle, for that is an almost passive organ, and utterly incapable of producing a sound, surpassing the first in clearness though not in duration. And, moreover, if my memory serves me right, Dr. Corrigan found, in an experiment which he performed, that both sounds were produced after the auricle had ceased to act. Dr. C. has wisely got over the difficulty by not attempting to explain the particular cause of each sound, but has written so generally, that through his whole paper I cannot find to which sound he is alluding.

Dr. C. says, that the motion of a fluid against a solid cannot cause sound unless there be some air present, or, at least, if the fluid and solid be always in perfect juxta-position; his sense of hearing must be very comfortably dull, if he can sleep with his head resting on the bottom of a boat when there is much swell upon the water.

Trusting that I have not been too prolix, and that you will, if convenient, insert these observations in your journal,

I am, sir,
Your obedient servant,
Robert Blyth.

7, Charterhouse Square,
March 29th, 1836.

He that hath not been versed in the operations of the Art, nor a frequent auditor of the Lectures of such as are learned therein, and sets forth himself for a brave Surgeon, for that he hath read much,—he is either much deceived, or impudent.—*Ambrose Paré.*

THE NITRO-MURIATIC ACID BATH.

To the Editor of the Medical Gazette.

Sir,

Under the above head, an extract, from Hufeland's Journal, having appeared in your last number, shewing the efficacy of the nitro-muriatic acid bath, as employed by M. Schlesinger, it may not be uninteresting to some of your readers to lay before them an account of the same remedy, which was put into my hands by the projector, the late Dr. Scot, twenty years ago, at which period, having returned from India, he made known his experience in the treatment of obstinate hepatic affections, by this process, as a substitute for mercury. I am not aware that Dr. Scot ever published any thing on the subject, with the exception of the printed document I forward to you; and as this bears, at the end of the sheet, his prescription for the ingredients, *in his own hand writing*, (which, in point of proportion, are so nearly similar to the one alluded to), I trust you will advocate the "Palmam qui meruit ferat," by the insertion of Dr. Scot's paper, with the date.

I have the honour to be, sir,
Your obedient humble servant,
A. R. Sutherland.

1, Parliament Street,
30th March, 1836.

Dr. Scot's Account of the Nitro-Muriatic Acid Bath.

As I am often applied to for the method of using this bath, and as, in spite of all the trouble I have taken, I frequently find that it is very badly managed, I have found it necessary to draw out, for the use of my friends, a short account of my mode of proceeding.

I have, at different times, used different proportions of the acids, but of late have mixed them in equal parts; but I propose in future to employ three parts of the muriatic to two of the nitric acid. This is the most powerful proportion that I have yet discovered.

On the mixture of the acids, a great volume of elastic gas is disengaged, which is extremely offensive, and which soon pervades every part of a house. In order to avoid this, the acids should be diluted with about twice their bulk of water. Put, then, the necessary quantity of water into a bottle or other glass vessel, and pour on

it the acids, one after the other. This may be kept for use in common wine-bottles. It is, however, generally right to have this diluted mixture of the acids made by the apothecaries or chemists.

I have frequently, in India, exposed the whole surface of the body below the head to the action of this acid bath. I have, however, found in this country, that it generally sufficient to *bathe the legs to the knees, or a little above them.* Get a wooden tub, just large enough to hold the feet at its bottom, and at top to contain the legs or knees. The bottom of such a tub should be wider than its top, for it is desirable, that in addition to the feet and legs, it should hold as little fluid as possible. If larger, the bath will be less easily warmed, and the expenditure of acid will be greater. To this tub a quart bottlefull of the before-mentioned acid mixture may be sufficient. This rule, however, is not enough, for the acids vary much in strength at different times, and the skins of people are affected differently. The taste affords another method of judging. The bath should be about as sour as very weak vinegar, and it should perhaps prick the skin slightly, after being exposed to it for half an hour. If stronger than this, it will produce troublesome pimples, and give a yellow colour to the nails and the skin of the feet, all of which should be avoided. A common wash-hand bason answers very well for bathing the feet, and sponging the legs at the same time.

The bath should be made agreeably warm by pouring into it a sufficient quantity of boiling water. In order to warm it, I have commonly thrown out about a third or fourth of it, replacing the loss by boiling water and a little fresh acid. This is perhaps the best method; but I have at times warmed it in glass or well glazed vessels of porcelain, put near the fire, or even over it. This should be done often, for it probably injures the bath.

"*I am not now convinced that a particle of* acid *enters the system! The effects arise, I suspect, from chlorine alone.*"

I was long anxious to procure a substitute for mercury, and for many purposes I found it at last in the nitro-muriatic acid bath. I have already in London seen enough of it to conclude, that it is not less efficacious than in India, and that it is capable of relieving, or of curing, a great range of disease; nor do these recent observations rest on my authority alone. If I can overcome the unwillingness of the medical world to try so new a remedy (and I cannot charge them with unreasonable scepticism in such a case), a confirmation of what I have asserted will appear in time from many quarters.

I shall only take notice at present, for it is particularly necessary, of a class of derangements which are very common. They are called *bilious*, and arise from the biliary secretions being too abundant, deficient, or depraved. Hence are produced disorders of the stomach, giddiness, feverish heat, and pain of the head, restless nights, cramp, melancholy, and many of those unhappy feelings to which the term nervous has been applied. In such cases, let the patient sit in the tepid nitro-muriatic bath for the legs, half an hour or less, according to circumstances, every night, or every second night. With some of these biliously disposed people, the first bath, and in a few hours, produces decided effects. It purges, gives rise to the expulsion of dark-coloured fæces or bright coloured bile, or bile of a brown, a green, or black colour, like tar mixed with oil. The pulse in time becomes quicker than natural, and a degree of restlessness takes place. These effects may be kept up for a number of days. They, however, are often much longer in appearing. Where the bile is deficient in quantity, the effects of the bath are only known by the fæces returning by degrees to their natural colour, and by a gradual improvement of the health. With people disposed to bile, it is necessary to keep the bowels very open during the use of the bath; for one of its effects, as I have said, and on which much of its beneficial tendency depends, is to produce a flow of bile into the intestinal canal. The immediate consequence of this is a feeling of being bilious, such as head-ache, giddiness, &c. &c. which should be obviated by laxatives. Those inconvenient effects of the bath arise from the very powers which enable it to correct some depraved conditions of the stomach and biliary organs. Although this bath, with little disturbance, produces many happy effects, let it not be supposed that delicate, or even strong people, suffer no temporary inconvenience. Let it always on the contrary be recollected, that the advantages produced by it can never be fully appreciated until the patient has given up the use of it for a considerable time. Even those who feel no very sensible effects from it at the moment, generally, in the end, find their health improved.

The great remedy at present for bile is calomel, or mercury in some form; but this it is necessary after a time to repeat. The very same thing is true of the bath. When the bilious feelings return, it must be repeated. Patients must themselves discover how long they can go on without its use, and when they return to it, two or three bathings of the legs, or washing the hands and arms for a few minutes with the nitro-muriatic liquor, or sponging the

body more largely, will generally be found to bring relief. The periods of health gradually become longer and longer, till a complete recovery of it is effected. If the bath were used cold, it would produce the very same effects as when warm; but in this climate it is certainly better and more agreeable to employ it tepid. Sponging the body with it has the same effects with bathing in it. For this purpose, put some tepid water into a bason with a proper portion of nitro-muriatic acid, and with a sponge moisten the thighs, legs, and abdomen, for ten or fifteen minutes daily; or these parts may be sponged alternately. With delicate people and those who are very sensible to this remedy, it is sufficient to put one hand among the diluted nitro-muriatic acid for a few minutes. Washing both hands with it and both arms for a few minutes daily, will in a short time be found sufficient to affect some bilious people, and to as high a degree as is prudent.

This remedy does occasionally open the bowels a good deal; but such an effect is not to be depended on, although its tendency in the end is to correct a disposition to constipation. The general error is that of making the nitro-muriatic liquor for sponging or bathing by much too acid.

London, Nov. 9, 1816.

R Aq. Fontan. ℥v.; Adde. Acid. Muriatic. ʒiij.; Acid. Nitric. ʒij. M.

Of this acid I put an ounce to each quart of tepid water for sponging or bathing.

VACCINATION IN THE EARLY MONTHS OF INFANCY.

To the Editor of the Medical Gazette.

Sir,

In your journal for April 2d, Mr. Aikin has written some observations on vaccination, wherein he considers the opinion I advanced, and supported by examples, on the influence of vaccine matter during the period of lactation, as fraught with danger. He says, "I hardly know any opinion that would prove a greater obstacle to the diffusion of the blessings of vaccination, than that of its inexpediency during the first nine months of infant life." Probably I erred in specifying the period of nine months; but from the mass of *facts* which have been presented to me on the subject, I still think it well to adhere to the principle as a general rule. From this it is not to be inferred that we are never to vaccinate a child under nine months old; circumstances such as Mr. Aikin has mentioned, as well as others, may frequently arise, so as to induce a medical man to make exceptions to this rule.

Since I first published the opinion as an observation, or recommendation, in the Medical Gazette for June 13, 1835, I see a most able account, delivered by Dr. Murray, at the South African Literary Institution, has been inserted in your journal for August 1, 1835, in which my ideas are fully borne out; it is a statement worthy the attention of all who feel with me how important it is to establish the great blessing of vaccination upon a right foundation.

Knowing Mr. Aikin's great experience on the subject, for self-justification I shall beg to make a few short quotations from Dr. Murray's paper; he says, "I have become impressed with the idea that vaccination in very early infancy is probably a principal cause of its failure, from reflecting upon the known insusceptibility of the infantile constitution to contagion in general, and from having had occasion to observe some very marked instances of its insusceptibility to scarlatina during the prevalence of that disease here in 1830, at which period, although children were chiefly the subjects of its attack, young infants generally enjoyed the privilege of exemption from it, as if their system were insusceptible of the morbific effect of its contagion. Dr. Underwood, who wrote specially on the diseases of children, states, that although the small-pox is a complaint so incident to early life, that comparatively few children living to the age of eight or ten years are found to escape it, yet it is not so readily communicated in the state of early infancy as hath been generally imagined, unless by immediate infection—*i. e.* by inoculation. 'Every one,' he observes, 'knows how very few infants he has heard of having received the small-pox naturally, though fewer of those are inoculated than of children above a year old; and this exemption from the natural small-pox does not seem to arise from their not being exposed to the ordinary means of contagion, especially among the lower and middling ranks of people, who form the bulk of mankind: the poor furnish frequent instances of the truth of this observation. I have attended where chil-

dren were born in an air saturated, as it were, with the miasm of this disease, and even lying continually in a cradle in which another child had died a few days before, and who have, nevertheless, escaped the disease, and sometimes when they have slept together in the same bed with one loaded with it.'"

Relative to the tabular account of deaths from small-pox, for the years from 1768 to 1774, as collected from the register of the collegiate church at Manchester, and recorded in the fifth volume of the Medical Observations and Inquiries, Dr. Percival observes, that from the said document it may be concluded that small-pox rarely occurs to children in the early part of infancy; experience showing that they are not much predisposed to receive it; and this conclusion is confirmed by Mr. Aikin, in his account of the variolous epidemic which raged with great violence in the town of Warrington, in 1773, as well as by the experience of Dr. Munro, who informs us, in his work on Inoculation, "that of twelve infants, whom he inoculated within a fortnight of their birth, not one had the variolous eruption." Mr. T. K. Deane, the secretary of the Cape Vaccine Institution, in answer to some inquiries on the subject, says—"With regard to persons who have been vaccinated here in infancy, and afterwards exposed to variolous contagion, a number are reported to have taken small-pox when they have gone to Europe for education, &c., but to have had it in a mild degree. Of these, I personally know eight, and I have heard of several others who became attacked in a similar way on going to India; but of those who were above four years of age when vaccinated, in 1803, when the cow-pox virus was first introduced into this colony, and who have subsequently gone to Europe, &c. not one has ever become affected with small-pox, as far as I know, and the number that I have ascertained to have been put to this proof is sixty-one: and one of them is a physician, who had just returned from Europe when the small-pox broke out here in 1812, and who was placed in charge of one of the Small-pox hospitals then established in Cape Town." I would also mention, says Dr. Murray, that when small-pox made its appearance in 1812, fifty-four government slaves were revaccinated here, as a precautionary measure, although they had all been subjected to the operation the first time the virus was introduced, in 1803, when they had already attained the age of puberty; and in no one instance did the second vaccination take effect, nor did any of them become affected with small-pox, although they were, on more than one occasion, exposed to its contagion." Dr. Murray thus concludes:—"According to my present opinion upon the subject, I would recommend vaccination to be deferred in infants till the fifth or sixth month."

Much more might be adduced, but I fear I have already trespassed at too great a length on your pages.

I remain,
Yours most respectfully,
JOHN GRANTHAM.

Crayford, Kent,
April 6, 1836.

SOME

MEDICO-LEGAL CASES OF RUPTURE OF THE BLADDER,

FROM BLOWS ON THE LOWER BELLY.

THE last number of the *Annales d'Hygiène et de Médecine Legale* (No. xxix. Jan. 1836) contains the following case:—

Two men having quarrelled in a Café, one of them seized the other by the hair of the head, shook him violently, planted a blow on the belly with his knee, and then threw him on the ground, where he kicked him in the same part of the body. The beaten man was lifted up, carried to bed, and died at the end of seven days. A medico-legal inspection of the body was ordered by the authorities, and MM. P. Guersent and Denis were entrusted with the examination. Their report contains many minute particulars; but the following may be considered as including all the chief points of importance.

The deceased was between 30 and 40 years of age, strongly made, his stature 5 feet, 6 or 7 inches (French). No trace of bruises about the face or head. The jaws locked. A large quantity of a dark red liquid flowing from the mouth. Cadaveric lividities on the anterior of the chest, also on the back part of the body (the deceased having died about twenty-four hours before inspec-

tion). Marks of a blister and of abundance of leeches on the hypogastric region. The abdomen distended, evidently containing fluid effused. Two slight excoriations about three inches to the right of the navel; another below the right inguinal ring; another in the right groin; and, finally, a fifth on the anterior and upper part of the left thigh, a little below Poupart's ligament. Cadaveric stiffness very considerable in the lower extremities.

No morbid appearances were found about the brain or its membranes; nor was there any thing worthy of special notice observed in the chest, unless, perhaps, that the lungs were gorged with black blood. In the bronchia and trachea was contained some of the same sort of liquid as issued from the mouth.

On opening the abdomen, a large quantity of sanguineous fluid issued forth, having an ammoniacal odour. The exterior of the stomach and intestines of a brownish colour, studded with red patches. Adhesions and false membranes among the intestines belonging to the lesser pelvis; particularly about the parts in connexion with the bladder, the cæcum, and the bowels in the neighbourhood of the right iliac fossa. The peritoneum much inflamed throughout, especially where the adhesions and membranes were formed. In the posterior and upper part of the bladder a vertical laceration was found, to the extent of about two inches. The paries was divided through and through, only in the lower half of the rupture; the upper half not involving the mucous membrane. The lips of the laceration were indented, or notched, and covered with a kind of false membrane; their vicinity was ecchymosed. The mucous membrane lining the interior of the bladder swollen, inflamed, and the inflammation limited to the neck of the organ. Stomach and intestines contain much greyish liquid; gall-bladder filled with blackish bile; liver, spleen, and other viscera, healthy.

The muscles of the abdomen corresponding to the hypogastric and umbilical regions examined with the greatest attention, layer by layer, did not present the least appearance of contusion. The excoriation already mentioned, examined in like manner, proved to be altogether confined to the surface.

"From all which appearances we infer, and have no hesitation to declare, that death was caused by rupture of the bladder; owing to which the urine escaped into the abdominal cavity, when it became a fatal source of inflammation, bidding defiance to all medical aid. We further assert that we have reason to believe the rupture originated in external violence inflicted on the hypogastric region *.

"Should it seem surprising to any one that a lesion so considerable could be produced in the bladder, without the parts in front of it being in the least contused, we can only say that it is perfectly *possible* — especially if the bladder were distended with fluid at the time of the infliction of the injury. The annals of surgery contain examples of the kind; and we beg to add that one of us witnessed the autopsy of a soldier who died in forty-eight hours after receiving the kick of a horse in the bottom of the belly; yet, though there was present a rupture of the small intestine, there was not the least mark of violence on the exterior of the abdomen."

In consequence of this *rapport*, proceedings were taken against the Sieur W., the person who had beaten and kicked the deceased. The indictment was for voluntary homicide; containing also a count for assault and wounds. The prisoner was found *guilty* on the latter count only, and was sentenced to 15 months' imprisonment, with damages 100 fr.

We shall now present the reader with a brief account of another case of ruptured bladder, very similar in many respects to the preceding, which occurred recently in this country:—

William Eccles was indicted, at Lancaster (March 28, 1836), for feloniously killing and slaying one James Hull, on the 29th November, 1835. The prisoner having been drinking, met Hull coming against him in the open road. Eccles desired Hull to "stand back;" upon which the latter remonstrated, and said that the road was wide enough for both. The prisoner then immediately *punned* (kicked) the deceased in the lower part of the belly, with a heavy iron-shod

* This inference must be derived from the circumstantial evidence; for there is nothing in the actual appearances of the body, as described, to warrant it. The reporters, indeed, endeavour to reconcile the fact of the rupture with the absence of external marks of injury; but they do not show that it might not have arisen from internal causes. —Ed. Gaz.

clog which he wore. Deceased became enraged with this brutal attack upon him, and both parties stripped to fight; but before they began, Hull tried to make water, but could not. He turned sick, said he was very ill, could not fight, and desired to go home. Having been supported for about two hundred yards with difficulty, he was unable to proceed further, and went down on his knees. A wheelbarrow was procured, in which he was placed, but the motion occasioned him so much pain that he was unable to proceed in that manner. Another mode of conveyance was therefore resorted to, and he was carried home in a chair. A surgeon was sent for, who administered some things, but the man died on the Friday following. The assault took place on the previous Sunday; so that death ensued on the fifth day. A *post-mortem* examination having been instituted, no mark of any external injury could be discovered, but the bladder was found ruptured; and this rupture, according to the medical evidence, was the proximate cause of the man's death. Two medical men testified to this fact. On their cross-examination, it was attempted to be shown, by counsel for the defence, that the rupture might have been occasioned by distension, from want of an ordinary discharge after much drinking, and that such was the most usual cause of that misfortune.

Lord Denman, in summing up the evidence for the jury, observed, that if the rupture was occasioned in the manner suggested by the defence, it was very extraordinary that it should happen at a time immediately after a violent kick had been inflicted on the part; though it was probable that the distension of the organ might have rendered the blow more dangerous. After retiring a short time, the jury returned a verdict of *guilty*, and the prisoner was sentenced to a year's imprisonment, with hard labour, in Lancaster Castle.

In the fourteenth volume of this journal will be found the particulars of another case of ruptured bladder, which was treated by M. Dupuytren. That eminent surgeon entertained hopes that nature would have effectually repaired the injury, by establishing a new reservoir for the urine; and was satisfied, from what he observed *post-mortem*, that this would have been the case, had not the patient caused his own death by gorging himself with improper food. Adhesions of cellular membrane were found, forming very firm bands, between the parietes of the abdomen, the lateral parts of the bladder, and the other viscera contained in the cavity of the lesser pelvis. Other bands formed a pouch behind the bladder, containing a turbid urinous fluid, mixed with flocculi of albumen. The bladder was torn to the extent of two inches at the postero-superior part, and in the direction of its greatest diameter.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue a abréger."—D'Alembert.

Elements of Medical Jurisprudence. By Alfred S. Taylor, F.L.S., Lecturer on Medical Jurisprudence and Chemistry in Guy's Hospital. Vol. I.

The subjects discussed in this volume are of high importance, and the ability of the author is conspicuous. He has diligently collected and methodically arranged a large stock of materials, bearing on some of the most interesting questions of legal medicine. Many still remain to be treated, which we shall be glad to find handled with the same zeal and talent in succeeding volumes.

We object to calling this work "Elements;" it consists of a series of disquisitions, or chapters of considerable length, chiefly on the various kinds of death, and on wounds; but there is nothing peculiarly elementary about it, at least as regards a systematic arrangement of the topics of forensic medicine. It should rather, we think, be entitled a collection of medico-legal essays.

In an introductory chapter, drawn up with much care, the author takes a comprehensive view of the objects and advantages of medical jurisprudence; its absolute necessity as a special branch of medical education; also the importance of a competent knowledge of it to persons of the legal profession. He shews the advantages arising to the state from its proper cultivation; and, on the other hand, the mischiefs resulting from its neglect. Of the latter he gives an apposite example:—

"Within a very recent period, out of six trials for homicide by poisoning and

cutting and maiming, which occurred in different parts of England, five ended in acquittals, because, as the judges observed in summing up the evidence, the opinions of the medical witnesses were of too speculative a character, and too conflicting with each other, to justify the finding of a verdict of guilty."

This want of steadiness and consistency on the part of professional witnesses, when called to give evidence in courts of justice, Mr. Taylor considers as mainly owing to the neglect of the parties—their gross deficiency, in short, in medico-legal acquirements. It is but too often forgotten that the gentlemen of the bar "constantly pursue a systematic course of examination, and generally succeed in obtaining verdicts for their clients, by drawing contradictory statements from the mouths of the professional witnesses." The strange oversight of the College of Surgeons, in so long omitting to introduce forensic medicine into the curriculum for their diploma, is very properly exposed by the author: we are sorry he did not mention that the College of Physicians has got the start of them in this respect—*medicina forensis*, as well as *practica*, being included in the new course of discipline required for the license.

In treating the subject of asphyxia, we are inclined to think our author needlessly diffuse. Were his volume professedly physiological, it would be very well and very proper to enter into the merits of the respective theories of Bichat, Legallois, Goodwyn, Kay, &c.; but essentially practical as it is, or ought to be, the more briefly, consistently with clearness, theory could be disposed of, the better. We like the manner, notwithstanding, in which Mr. Taylor acquits himself of his difficult task; and we will present the reader with what he says towards the conclusion.

"From all that has been previously stated, it appears to me we are justified in concluding, that if, in the state of asphyxia, venous blood possess any power of nourishing or stimulating the nervous system, this power has not been shewn to exist in it; at least this must be our conclusion so far as concerns man, to whom, be it remembered, our observations are now chiefly directed. According to Dr. Kay, the cerebral disturbance arises partly from the diminution in the quantity of blood circulated, and partly from the asphyxiated blood being less capable of maintaining the organic motions of the nervous system. He admits that were this fluid to circulate freely through the brain, its functions would ere long be suspended from the want of stimulus and nourishment. Now we contend that the deficiency in the quantity of blood is not a cause, but a consequence, of the cessation of the functions of the nervous system; that the cerebral disturbance proceeds from the want of its usual stimulus to the brain, namely, the arterial fluid; and that this disturbance takes place on the moment that the venous blood reaches that organ. Life, therefore, according to this view, does not cease in asphyxia because the circulation is arrested in the lungs, but because the functions of the nervous system are destroyed; this destruction, as first explained by Bichat, being antecedent to the stoppage of the respiratory process."

That part of the chapter on real and apparent death, which describes the phenomena of *putrefaction*, is valuable, as containing a summary of the principal circumstances which always more or less modify that process; but we could have wished brevity had been more consulted in the previous part, where the vulgar signs are so largely discussed. The Hippocratic face, for example, might well have been abridged, or dispensed with, especially as Mr. Taylor did not go to the original for it; he borrows it from Foderé, who had an unhappy knack at exaggeration: the Strasburg professor introduced features into the moribund face, which the old Coan himself would scarcely have recognized. Foderé, besides, is often wrong in his quotations; and Mr. T. had done well had he omitted the reference in the present instance.

Death by drowning occupies a chapter full of excellent matter; the illustrations being derived from a variety of sources, chiefly modern and national. In fact, no book has hitherto appeared worthy of comparison with our author's in this respect, his cases in point being always appropriate, and calculated to produce conviction.

Having dispatched hanging, strangulation, and suffocation, in a chapter of no mean length,—the subject of those other causes of death, lightning, cold, starvation, and fire, are disposed of.

The following passage, concerning

the probable cause of death by *lightning*, we are tempted to extract:—

"Many attempts have been made to determine, by experiments with the battery, the precise mode in which electricity destroys life. Mr. Singer found, that a strong charge passed through the head, gave him the sensation of a universal blow, followed by a transient loss of memory and indistinctness of vision. Müncke states that he saw an instance, where a full-grown man, who had received in his arms and thorax the charge of a jar of not more than two square feet capacity, fell, and remained in a state of perfect insensibility for an hour; and he remarks, that the full charge of a jar, of ten square feet capacity, would probably suffice to cause instant death in an adult, if the shock were transmitted through the head. There is some difficulty in performing these experiments on animals, because the electric fluid very often disperses itself over the surface of the body, instead of traversing the interior; and, of course, in such a case, it is unattended with any particular effects. The results of such experiments, however, where they have succeeded, show that the chief influence of this agent is confined to the cerebro-spinal system. A charge passed through the head of a bird was found to destroy the functions of the optic nerve, and induce perfect blindness. If a moderately strong charge be passed down the spinal column of a person standing, there is commonly such a prostration of strength that he falls to the ground. If a charge be passed through the whole length of the body of an eel, the animal is instantly killed; but when only a part of the body receives it, the destruction of irritability is confined to that part.

"Such are the consequences of the passages of a current of electric fluid through the body: but the facts will scarcely allow us to form a conjecture as to the mode in which it causes death. That the nervous system is the part chiefly, if not solely, affected by it, can be hardly doubted; and when we say that it is by the shock, or violent impression thus produced, that life is extinguished, we advance as far as the present limits of our knowledge will allow us in attempting to explain its fatal operation on the body. How the electric fluid acts upon the molecules of the brain and nerves it is impossible for us to determine."

If our limits permitted we could select many other excellent passages: but we must be content with announcing that there are such, copiously interspersed through the volume. Viterbi's case, by the way, ought not to have been given as one illustrative of the effects of fatal abstinence: that worthy contrived to dispatch himself with arsenic; his story is now well known on the continent.

The sixth chapter commences the intricate subject of wounds, which is also continued in three succeeding chapters; and so the volume closes. We should not omit to notice, however, that the "legal relations of wounds" form an important termination to the present portion of the work.

In a second volume, Mr. Taylor informs us, he will treat of toxicology, fœticide, infanticide, and insanity. We can only say, that we shall greet his appearance, whenever he returns to us with fresh acquisitions, gathered in the medico-legal field: his present visit has given us much pleasure. We are satisfied that the work, when complete, will constitute an elaborate system, well adapted for being consulted with advantage by practitioners who desire to be thoroughly acquainted with the principles of legal medicine.

MEDICAL GAZETTE.

Saturday, April 9, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

RUMOURS ABOUT THE NEW UNIVERSITY.

As the time draws nigh when the Warburtonian budget will be opened—if, indeed, it will be opened this session at all—the appetite of speculation is more sharp set than ever, and great is the longing to find out what it contains. An *honourable* contemporary of ours made every effort, by fair means or foul,

to obtain a sight of the invoice, or bill of fare: he did not succeed, and thereupon waxed very wroth; but he has since prudently become more calm, seeing that his blustering did no good. For our part, we are content to abide the event, and patiently to see what the "heart of the mystery" means; for time will disclose all.

Meanwhile it is amusing to observe the proceedings of the expectants, and to mark the phases which their opinions undergo, according as they seem likely to be or not to be realized. The one-faculty people, as many as remain of that over-sanguine set, which made so much noise about two years ago, know not what to think of the so much talked of scheme of a metropolitan University; they are taken all aback at the idea that it is to be only a University after all, and that degrees in medicine only, not in surgery or pharmacy, are to be conferred in it. They see no signs of their tripartite Board, which was to work such wonders, and to astonish all Europe. They are silent, and shake their heads, but still seem to have a lurking hope that all is not to be despaired of, since Mr. Warburton has not yet declared his plan.

The more moderate party, that called for a University in London, in order that this metropolis should possess facilities which Edinburgh and Dublin have long enjoyed, are almost equally puzzled as to the issue of their anxious anticipations. They do not despair, indeed, of the result, but they doubt whether the scheme will be carried into effect as satisfactorily as they had fondly hoped. Rumours are afloat which, not without reason, give them uneasiness. The management, it is whispered, is to be placed in hands incompetent and obscure; and who would not grieve if this were to be the case, in a city the first in Europe, and where, if any where, those talents abound suited to throw a lustre on any great national undertaking? Must intriguing mediocrity, and an amiable amateurship in science, entitle certain parties to a seat at the council-board of an institution on the success of which the character of the country is in some measure staked? What a laughing-stock to our continental friends shall we afford, if the Metropolitan University of Great Britain turn out to be a job—a mere humbug! Well may the once sanguine advocates of the original project lament the frustration of their warmest wishes.

We have already noticed the reports which are abroad regarding the alleged intention of those who have a voice in the management, to exclude from the examining body all who belong to any hospital or medical school; in short, to hold disqualified all hospital physicians and lecturers, admitting only, as competent, those who are engaged in private practice, and have no connexion with the business of teaching. The downright absurdity of this design we took occasion to point out not long since; and it gives us some satisfaction to find, that one of our contemporaries—himself erewhile among the hottest of the so-called liberal party—expresses opinions on this subject as nearly as possible identical with our own. "Such an exclusion," says the Editor of the Medico-Chirurgical Review, in the number just published, "would be highly detrimental to the interests of science. The men thus proscribed are those who are best qualified to test the candidates in the minute elementary knowledge which alone such candidates can be expected to possess. The very circumstance of being engaged for years in extensive private practice, would incapacitate the most talented private practitioner for the task of examining minutely into the acquirements of the

candidates in anatomy, chemistry, botany, and other branches of elementary knowledge. If the examinations were conducted in public, or in the written documentary manner, no unfair play, personal jealousy or partiality, could possibly influence the acceptance or rejection of the candidate. . . . . It would be monstrous to exclude a man from *testing* elementary knowledge, because he is in the daily habit of *teaching* it in all its minutiæ!"

But this is not the only rock of offence with which the managers are about to do mischief to themselves and others: there is another; and one, it must be confessed, very outrageously offensive. We allude to the monopoly which, it is strongly rumoured, is about to be conferred on King's College and London University. Every candidate, it is said, who seeks honours in medicine from the University Board, will be required to bring with him, from either of the establishments just named, certain certificates of general education. Now both these establishments being at the same time medical schools, a monopoly, by this arrangement, is clearly secured to them. If students of medicine must attend a particular school for general purposes, where simultaneously they may obtain their professional education, that school is clearly marked out as exclusively the one suited to their object, and all others, by consequence, as naught, and to be eschewed. It is not possible that this unjust measure can be finally adopted: it is fraught with iniquity to so many parties, that it cannot fail to excite a strong, and we hope a successful, opposition. Why not allow a general preliminary education to be procured wherever it conveniently can—whether at Harrow, Westminster, Eton, or any of the metropolitan seminaries—when the amount and sufficiency of that education could be so readily tested by a suitable examination? But no; we fear there is no likelihood of gaining any thing by reasoning with the managers whom we have to deal with: the manner of dealing with them is by remonstrance and strong protest.

We have just said that a befitting general education might be procured any where: we would have no objection to its being wholly of home growth; but wherever this preliminary general knowledge is obtained, matters not, so as it is really obtained; for that can be fully ascertained by a proper examination. No certificate of the particular school or school-master need be insisted on. But we carry not this principle into our views of *professional* education: here there must be evidence of certain courses having been gone through—certain manipulations performed under competent guidance—certain hospital attendances properly complied with. The visionary, insane notions, of those who contend that certificates should be abjured altogether, is highly ludicrous, and would deserve to be treated only with ridicule, were there not reason to suspect that a dishonest motive of self-interest is at the bottom of their counsels. Abolish schools and hospitals, as places of education, and where will the candidates for diplomas qualify themselves for examination? In the grinder's workshop: and we rather suspect that the worthy grinders are at the root of this grand scheme of certificate abolition. We shall conclude these remarks with one other passage from the writer already cited: he thus describes the disadvantages and absurdities of the scheme. "We would ask these men how a student can be properly tested by an *examination* in anatomy, chemistry, surgery, and more especially in *clinical* knowledge, by such examination? It is utterly impossible. We grant, indeed, that examinations might be made much more efficient and search-

ing than they now are; but still they would be grossly imperfect, without the aid of other checks, which will be presently pointed out. A student may, by dint of hard study, and the aid of a *grinder,* be capable of describing the origin and insertion of every muscle, the ramification of every artery, and the distribution of every vein; and yet if taken into a dissecting-room, he might be scarcely capable of distinguishing the sciatic nerve from the sartorius muscle. He may be able, from books and grinding, to lay down the diagnosis, prognosis, and treatment, of every disease in Good's Nosology; and yet, if taken into the wards of an hospital, he might not be capable of distinguishing small pox from measles."

THE NEW COLLEGE COUNCIL.

In our list of the new Council of the College of Physicians, published last week, the name of Dr. Bright was introduced by mistake, and that of Dr. Seymour omitted. Thus corrected, the catalogue is as follows:—

Sir H. Halford, *Pres.*

Dr. Heberden.	Dr. Chambers.
Dr. Turner.	Dr. Elliotson.
Dr. Hue.	Dr. Watson.
Dr. Paris.	Dr. Seymour.
Dr. Macmichael.	Dr. Holland.
Dr. P. M. Latham.	Dr. Clendinning.

MURDEROUS QUACK PILLS.

We give, in a subsequent page, the horrible details of another case of fatal quackery. The quack delinquent, in this instance, was one of the "Hygeian" agents—an ignorant, impudent, lying vendor of Morison's pills, who dispatched his victim—a Captain Mackenzie, aged only 32, and in robust health — with the coolest deliberation. He was defended with all the ability of Sir Frederick Pollock, and Messrs. C. Phillips and Adolphus; and it is evident that the arch-quack Morison spared no expense to procure his acquittal. Yet he was found *guilty*, but recommended to mercy on the ground of his being merely the vendor—not the compounder of the pills. Why is not Morison himself, then, put in the dock? If these repeated verdicts do not open the eyes of the public, their case is deplorable; they are the doomed victims of the most infamous of mankind,—those who live by procuring the disease and death of their fellow men.

"RODERICK MACLEOD'S BREAD PILLS."

To the Editor of the Medical Gazette.

Sir,

Mr. Wakley, who devotes to slandering the humble individual who addresses you, all the time he can spare from his parliamentary duties, has honoured me, in the last number of his journal, with some especial abuse, on account of my supposed opposition to some scheme of his, called an "Anti-Medical Quackery Society," about which I know little, and care less, and concerning which I have never expressed any opinion at all. The jist of the article alluded to, consists in a charge against me of quackery, in having "practised under the garb of secrecy;" to which is added the enormity of "making use of Latin terms," and even of "mysterious signs," in writing my prescriptions. But probably these atrocities would not have brought down the virtuous indignation of Mr. Wakley with so heavy a hand, had I not (query "under the garb of *secrecy?*") printed a set of formulæ, among which was one for bread pills. Now, as the editor of the Lancet has frequently referred to this as something very disgraceful, I should have explained the circumstance in which it originated sooner, but that I had no copy of the document, and feared to quote it from memory. From this difficulty Mr. Wakley has fortunately relieved me, by the publication of the prescription, and as it was written nearly twenty years ago, I may be allowed to observe, that the care with which he has so long preserved it, and the use he has now made of it, form a striking commentary on the purity of his motives.

The history of "Roderick Macleod's formula for bread-crumb prescriptions," is simply this:—When I was appointed physician to the Westminster Dispen-

sary, Mr. Coman (then an old man) was the apothecary, and had been so since the establishment of the charity, in 1774. His faith in physic was as unbounded as the quantity of it which he administered: let the physicians or surgeons order what they might, he always added something of his own; by which he kept up a perpetual drain at once upon the constitutions of the patients and the funds of the Dispensary. Many expedients were tried, to break the old gentleman of this habit, but in vain; for he had long had the chief care of the patients himself, by which he had acquired a certain reputation among them, which he was anxious to maintain; and this could only be done by appearing to take a part in the management of their cases. At last I compromised the matter with him, and had a drawer assigned to "*Pilulæ ex Mica Panis;*" which he had permission to administer *pro re nata.* Many of the patients had got into the habit of taking medicine frequently during the day, and thought themselves neglected if the supply were much curtailed. This led to my occasionally giving the bread pills in addition to such efficient remedies as the cases required: and it was amusing to listen to the account given by some patients of the effects which those same pills produced, particularly, as might be expected, on nervous and fanciful persons. So far, probably, it will be thought that I had scarcely done any thing to justify Mr. Wakley's charge of employing the pills "as instruments of fraud and extortion." But, alas, the atrocity went further: at the time to which I allude, there were a considerable number of pupils at the Dispensary; at their request I made out a list of the formulæ chiefly used, and among the rest, that for the *pilulæ ex mica panis* was included, while a statement of their virtues was appended, in mock solemnity.—Here it is.

"PILULÆ EX MICA PANIS.

"℞. *Micæ Panis* ℥i.

"*Divide in pilulas* xii. *quarum una sumatur ter quotidie.*

"These pills are extremely useful in *convalescence* from almost all diseases, and *with due attention to diet and regimen* will frequently remove many obstinate complaints, such as hypochondriasis, hysteria, dyspepsia, and amenorrhœa. Some care, however, is required in their exhibition, as a considerable number of instances have occurred at the Westminster Dispensary, in which patients *have complained much of the severity of their effects!*"

Now this may have been but an indifferent joke, and I am not disposed to defend it on the score of taste. The proceeding, too, I admit, may have been a *young* one even in a physician of 23; but be it remembered, in extenuation of the imprudence, that the Lancet was not then in existence, and that the extent to which dishonesty and hatred are capable of stimulating detraction, wanted the illustrations it has since received.

Soon afterwards the old apothecary became superannuated, and was succeeded by Mr. Wade, a well-educated and intelligent man, with whose appointment the necessity for the bread-pills no longer existed; so that the drawer soon became empty, and never was replenished. Such is the whole history of this mighty affair,—such the foundation on which I have been accused of every infamy calculated to reflect disgrace on my professional character.

Allow me to add, that it is not my intention again to depart from the rule I have hitherto invariably followed, of leaving, unnoticed, the attacks upon me, which appear in almost every number of the Lancet; for I believe that the motives and character of the party from whom they proceed are so generally known, as to render any refutation superfluous—and, indeed, the above is the only charge which has had even the shadow of a foundation to rest upon. Mr. Wakley's present phrenzy—for to nothing less does it amount—has evidently been produced by certain recent castigations, emanating, however, from an abler pen than mine.—I am, sir,

Your obedient servant,

R. Macleod.

23, Henrietta-street, Cavendish-square,

MECHANICAL PHILOSOPHY AS APPLIED TO MEDICINE.

Abstract of Lecture Second: as delivered at the Aldersgate School,

By Dr. Birkbeck.

Dr. Birkbeck began by observing, that obvious and easy as the practice of locomotion in the human subject might appear, it would be found, if minutely investigated, curious and complicated. The will directs a certain change of place, and

immediately an extensive apparatus is brought into action, and the purpose is accomplished. All this occurs, it must be observed, without the individual being at all aware of the muscles employed; nay, even, better perhaps, with perfect ignorance of the precise instruments required for effecting the action, than if it were attempted to produce the same effect anatomically. In the act of respiration it has been said that about one hundred muscles co-operate, yet no one can be supposed to direct the several movements. If it be alleged, that this is an instance of involuntary motion, and, therefore, is otherwise arranged, we may take, as an example, articulate utterance; the method by which the mind of the speaker is diffused through his audience; a procedure perfectly voluntary, and yet demanding the co-operation of a still greater number of muscles. It must at last be referred to some influence such as we term instinct, for imitation, in the full sense of the word, it cannot be; and we cannot, perhaps, give a better account of the matter, than is given by Milton, in the beautiful description by Adam, of the impulses and movements which followed the first dawning of conscious existence.

Dr. Birkbeck then proceeded to apply the statical and dynamical principles advanced in the preceding lecture, to the explanation of the position and motions of the body. He first considered several circumstances presented by the skeleton, the frame work or scaffolding, beginning with the head. He shewed that its configuration was adapted to protection: that as a firm, arched structure, it was admirably calculated to defend its important contents from injury by pressure. Besides it was shown that the flat portion of the temporal bones, with the two petrous portions, answered the purpose of a tie bearer in ordinary roofs; preventing especially the parietal bones, the sides of the dome, from expanding by pressure. The peculiar structure of the basis of the cranium was noticed; and the motion of the head on the atlas, exhibiting curvage of the first species, was particularly described. In speaking of the rotation of the head by means of the vertebra dentata, a mistake of the liberal and enlightened theologian, Dr. Paley, was pointed out. Between the atlas "and the bone next underneath it, there is (he says) a mechanism resembling a *tenon* and *mortice*." Now that this mechanism does not resemble a tenon and a mortice, was proved by exhibiting a piece of wood fitted into another piece, according to the meaning of the terms, as then explained. As a tenon is always fixed in mortice, and is a prism, it cannot with propriety be said, "when we turn the head round, we use the tenon and mortice which runs between the first bone of the neck and the second." The manner in which the pivot-hole for the tooth of the second vertebra is formed, and the effectual mode in which the spinal cord is preserved from pressure, were then displayed; and the admirable adjustments to a multitude of necessary, yet somewhat opposite purposes, in the construction of the spinal column—mechanism of the most consummate excellence—were detailed with considerable minuteness.

Several points of great interest were unavoidably passed over for want of time, in order to commence a description of the mechanical circumstances belonging to the extremities. The shoulder-joint, a ball and socket, having certain peculiarities, was first noticed, and then the construction of the elbow. Dr. Birkbeck attended particularly, in regard to this joint and that of the wrist, to the change of supination and pronation, effected by the mode in which the radius and ulna are respectively articulated: a change which could in no other way have been so promptly and commodiously effected. The valuable ends answered by levers of the third kind, the kind of levers employed in producing the motions of the fore-arm on the arm, were announced; and the objects to be gained by the introduction of a number of small bones betwixt the fore-arm and the fingers—the prevention of vibration, and occasionally of severe shocks, in using the hand—were theoretically and practically deduced. After noticing the simple joints of the fingers, the joints of the human fabric were generally examined. A hinge-joint was shewn to differ essentially from a common unorganized hinge, having no pin passing through it, but a beautifully constructed capsular ligament answering that purpose.

The self-lubrication of the animal joint was pointed out, and the admirable adjustment of the quantity of synovia, or joint-oil; so that for a long series of years, excepting when *hydrops articulorum* occurred, there never appeared to be any redundancy. An attempt to imitate this self-lubrication, in the ingenious axles of Collins and Birch, and in the admirable ball and socket hinge of the former eminent mechanic—suggested, as he often confessed, by the form of the hip-joint of a fowl—was noticed, and their inferiority as to lubrication declared. After which the peculiar and powerful influence of the pressure of the atmosphere in preserving the surfaces of the head of the thigh-bone, and the cavity of the acetabulum, in contact so firm as to be with difficulty overcome, was fully asserted. In order to render intelligible the plan of restoring the

body to an upright position, and preserving it in that position, the nature and operation of the centre of gravity, or centre of inertia, was experimentally demonstrated; and after taking a somewhat different view of the uses of the patella, ascribing much of its efficacy to its acting as a rigid shield placed firmly over the knee joint when drawn upwards by the extensors of the leg, Dr. Birkbeck concluded with a description of the mechanism of the ankle and the foot, in conjunction with the muscular forces by means of which they are exercised.

This second lecture was attended even by a larger audience than the preceding one. The subject of the third (to be delivered this evening) will be Animal Hydraulics.

COLLEGE OF PHYSICIANS.

The following is the paper on Coup de Soleil, which we mentioned was read at the last evening meeting of the College:—

On Coup de Soleil. By J. J. Russell, Esq. 73d Regiment. Communicated by Dr. J. Wilson.

I was led, by the following circumstance, to reflect on the nature of "Coup de Soleil;" which, as well as I can recollect, is treated of by all authors, and is generally considered to be, nothing more or less than true apoplexy, produced by the direct influence of the sun's rays; that its pathology is the same, and its mode of treatment similar—that is, that all the efforts of the medical attendant should be directed to the *head*, as the chief, nay, almost the only, seat of the disease: and here it strikes me a fallacy exists, leading to erroneous principles of practice.

In May, 1834, while I was in medical charge of the 63d regiment (a fine corps, composed of men in robust health), then recently arrived at Madras, the funeral of a general officer took place; to which, unfortunately, the men were marched out at an early hour in the afternoon, buttoned up in red coats and military stocks,—at a season, too, when the hot "land-winds" had just set in, rendering the atmosphere dry and suffocating even under shelter of a roof, and when the sun's rays were excessively powerful. The consequence was, that after proceeding two or three miles, several men fell down senseless. As many as eight or nine were brought into hospital that evening, and many more on the following day; three died—one on the spot, and two within a few hours. The symptoms observed (and they were alike in these three cases) were, first, excessive thirst, and a sense of faintness; then difficulty of breathing, stertor, coma, lividity of the face, and in one, whom I examined, contraction of the pupil. The remainder of the cases, in which the attack was slighter, and the powers of reaction perhaps greater, or at all events sufficiently great, rallied; and the attack in them ran on into either an ephemeral or more continued form of fever. The symptoms of these three cases did not more closely resemble each other, than did the "post-mortem" appearances. The brain was, in all, healthy; no congestion or accumulation of blood was observable; a very *small* quantity of serum was effused under the base of *one*, but in all three the lungs were congested even to *blackness* through their entire extent; and so densely loaded were they, that complete obstruction must have taken place. There was also an accumulation of blood in the right side of the heart, and the great vessels approaching it. A tumor was found in the right side of the thorax of one of the men, (Brennan); it was attached to the upper surface of the diaphragm, pressed against the right side of the heart, and intruded on the space which should have been occupied by the lung. It was six inches in length and four in breadth, consisted of a cyst, with a reflection of the pleura for an outer coat, and contained twenty two ounces of a straw-coloured serum. During the man's life there was no suspicion of the existence of such a powerful predisposing cause to the disease which terminated his life. He was a thin muscular man, remarkably active, and not at all of an apoplectic habit*.

Now, I think it may be fairly inferred, that death arose from the *obstructed* condition of the *lungs:* the whole column of blood being thrown suddenly, and with force, upon these organs, surprises them; it continues to flow with impetus, and in such a quantity, as to overpower them. They are unable to regain their elasticity, or throw off the load, and *suffocation* is the result; so that, instead of extravasation, or pressure on the brain, there is a deficiency of blood in that viscus. The existence of the tumor in Brennan's case only strengthens my conjecture.

It thus appearing, that the first and chief seat of mischief in "coup de soleil" is in

---

* I being too ill at the time to enter the dead-house, the post-mortem examinations were made by Dr. Mortimer, surgeon of the General Hospital, who kindly attended, and sent the parts to me in the adjoining house for inspection. As he is a most accurate observer, I was the better pleased that he should have witnessed the appearances.

the cavity of the *chest*, and not in the *head*, our remedial agents should be immediately directed to that part; efforts should be made to relieve it of the incumbrance with which it is blocked up, and to restore the circulation, — and thus the just relation would be retained which should ever exist between the morbid condition, the symptoms, and the treatment.

At the same time it must be observed that, as soon as re-action shall have been established it will be necessary to guard the brain against the force of a suddenly restored circulation. But this is to be looked upon only as a secondary effect of "coup de soleil."

These brief observations are offered chiefly with a hope of drawing the attention of more competent judges to the subject, and of assisting to throw some light upon other disorders of the *cerebral* functions, caused, apparently, by disease of the lungs.

OBSERVATIONS, ILLUSTRATIVE

OF

RENAL DISEASE

ACCOMPANIED WITH THE SECRETION OF ALBUMINOUS URINE.

BY DR. BRIGHT.

The importance and extensive prevalence of that form of disease, which, after it has continued for some time, is attended by the peculiar changes in the structure of the kidney, now pretty well known by the names of 'mottling,' 'white degeneration,' 'contraction,' or 'granulation,' impresses itself every year more and more deeply on my mind; and whether I turn to the wards of the hospital, or reflect on the experience of private practice, I find, on every side, such examples of its fatal progress and unrelenting ravages, as induce me to consider it amongst the most frequent as well as the most certain causes of death in some classes of the community, while it is of common occurrence in all; and I believe I speak within bounds, when I state, that not less than five hundred die of it annually in London alone. It is, indeed, a humiliating confession, that, although much attention has been directed to this disease for nearly ten years, and during that time there has probably been no period in which at least twenty cases might have been pointed out in each of the large hospitals of the metropolis—and there is reason to believe that double that number may, at this moment, and at all times, be found in the wards of Guy's Hospital—yet little or nothing has been done towards devising a method of permanent relief, when the disease has been confirmed; and no fixed plan has been laid down, as affording a tolerable certainty of cure in the more recent cases. I believe that our want of success, in what are considered the more recent attacks, is frequently owing to the fact, that the disease is far more advanced than we suspect, when it first becomes the object of our attention: and I am most anxious, in the present communication, to impress upon the members of our profession the insidious nature of this malady, that they may be led to watch its first approaches, with all the solicitude which they would feel on discovering the first suspicious symptoms of phthisis or of epilepsy. There is great reason to suppose that the seeds of this disease are often sown at an early period; and that intervals of apparent health produce a false security in the patient, his friends, and his medical attendants, even where apprehension has been early excited.

The first indications of the tendency to this disease is often hæmaturia, of a more or less decided character: this may originate from various causes, and yet may give evidence of the same tendency: scarlatina has apparently laid the foundation for the future mischief: exertion in childish plays has done the same; or it has sometimes appeared to be connected with suppressed catamenia. Intemperance seems its most usual source; and exposure to cold the most common cause of its development and aggravation. It is, however, more particularly to those causes which operate in youth, or are apparently so casual as to tempt us to believe that when the immediate symptoms are subdued no evil can result, that I wish to direct attention. Where intemperance has laid the foundation, the mischief will generally be so deeply rooted before the discovery is made, that, even could we remove the exciting cause, little could be hoped from remedies; but at the same time, a more impressive warning against the intemperate use of ardent spirits cannot be derived from any other form of disease with which we are acquainted; since, most assuredly, by no other do so many individuals fall victims to this vice.

The history of this disease, and its symptoms, is nearly as follows:—

A child, or an adult, is affected with scarlatina, or some other acute disease; or has indulged in the intemperate use of ardent spirits for a series of months or years: he is exposed to some casual cause, or habitual source, of suppressed perspiration: he finds the secretion of his urine

greatly increased, or he discovers that it is tinged with blood; or, without having made any such observation, he awakes in the morning with his face swollen, or his ankles puffy, or his hands œdematous. If he happen, in this condition, to fall under the care of a practitioner who suspects the nature of his disease, it is found, that already his urine contains a notable quantity of albumen: his pulse is full and hard, his skin dry, he has often headache, and sometimes a sense of weight or pain across the loins. Under treatment more or less active, or sometimes without any treatment, the more obvious and distressing of these symptoms disappear; the swelling, whether casual or constant, is no longer observed; the urine ceases to evince any admixture of red particles; and, according to the degree of importance which has been attached to these symptoms, they are gradually lost sight of, or are absolutely forgotten. Nevertheless, from time to time the countenance becomes bloated; the skin is dry; headaches occur with unusual frequency; or the calls to micturition disturb the night's repose. After a time, the healthy colour of the countenance fades; a sense of weakness, or pain in the loins, increases; headaches, often accompanied by vomiting, add greatly to the general want of comfort; and a sense of lassitude, of weariness, and of depression, gradually steal over the bodily and mental frame. Again the assistance of medicine is sought. If the nature of the disease is suspected, the urine is carefully tested, and found, in almost every trial, to contain albumen, while the quantity of urea is gradually diminishing. If, in the attempt to give relief to the oppression of the system, blood is drawn, it is often buffed, or the serum is milky and opaque; and nice analysis will frequently detect a great deficiency of albumen, and sometimes manifest indications of the presence of urea. If the disease is not suspected, the liver, the stomach, or the brain, divide the care of the practitioner, sometimes drawing him away entirely from the more important seat of disease. The swelling increases and decreases; the mind grows cheerful, or is sad; the secretions of the kidney or the skin are augmented or diminished, sometimes in alternate ratio, sometimes without apparent relation. Again the patient is restored to tolerable health, again he enters on his active duties; or he is perhaps less fortunate: the swelling increases, the urine becomes scanty, the powers of life seem to yield, the lungs become œdematous, and, in a state of asphyxia or coma, he sinks into the grave; or a sudden effusion of serum into the glottis closes the passages of the air, and brings on a more sudden dissolution. Should he, however, have resumed the avocations of life, he is usually subject to constant recurrence of his symptoms; or again, almost dismissing the recollection of his ailment, he is suddenly seized with an acute attack of pericarditis, or with a still more acute attack of peritonitis, which, without any renewed warning, deprives him, in eight and forty hours, of his life. Should he escape this danger likewise, other perils await him; his headaches have been observed to become more frequent; his stomach more deranged; his vision indistinct; his hearing depraved: he is suddenly seized with a convulsive fit, and becomes blind. He struggles through the attack; but again and again it returns; and before a day or a week has elapsed, worn out by convulsions, or overwhelmed by coma, the painful history of his disease is closed.

Of the appearance presented after death, enough will be said in another part of the present communication: but one question may be asked in this place—Do we always find such lesion of the kidney as to bear us out in the belief, that the peculiar condition of the urine, to which I have already referred, shows that the disease, call it what we may, is connected necessarily and essentially with the derangement of that organ? After ten years' attentive (though, perhaps, I must not say completely impartial) observation, I am ready to answer this question in the affirmative; and yet I confess that I have occasionally met with anomalies which have been somewhat difficult to explain.

I have certainly seen one or two cases, and have read statements of one or two more, in which the condition of the kidney would have led me to expect albuminous urine, but in which it had not been found to exist. In all these cases, however, the observations on the character of the urine have been made only a few days or weeks before death, at the close of a protracted illness; or the disease of the kidney has been complicated with other very extensive disease. A case occurred under my care, in the Clinical Ward, this winter, where a man died with ascites and a complication of most extensive disease of the liver and peritoneum, with moderately-advanced granulation of the kidney; yet it was only by the most careful examination that any traces of albumen could be detected in his urine: and this leads me to observe, that the secretion is apt to undergo changes, even after the structural disease is established; which renders it requisite that we should not be content with examining the urine on one or two occasions, if we have any reason to suspect the ex-

istence of this disease. In the first place, it is quite certain that if, from any cause, the urine becomes alkaline, the application of heat generally fails to produce coagulation; and in the next place, there has appeared to me to be an occasional alternation in the secreting power of the kidney; so that a large quantity of the lithates, or of crystallized lithic sand, is deposited, and the albuminous matter is not thrown off. I have this winter had a case of this kind likewise under my care, in a man whose symptoms bear all the character of renal disease, complicated with the disease of other viscera. His urine for several weeks was found to be distinctly albuminous: it then became loaded with the lithates; and now throws down abundant crystals of lithic sand, and no longer affords any trace of albumen: and mentioning this case to Dr. Addison, I was told that very lately the converse of this had shown itself in a case to which he had been called. All the symptoms led him to suspect this peculiar form of renal disease; but the urine did not coagulate, and was loaded with lithates. After a short time, the lithates disappeared, and now the albumen is very decidedly perceived in the urine. That such facts as these tend, in some degree, to render the presence of albumen in the urine, or its absence, a less unerring test, cannot be doubted; but these anomalies are so few as to interfere very little with the general fact: and after all, in the present state of our knowledge, how few of our diagnostic marks are not more or less under the influence of the casual complications of disease. There is no doubt, likewise, that the morbid condition of the kidneys connected with this disease varies, in different cases, to such a degree as to lead to the belief that the action from which the change has resulted must at least be modified by circumstances and constitutions. The kidney is sometimes simply contracted and hardened; sometimes loaded with an adventitious deposit; sometimes apparently degenerated throughout its whole texture; sometimes affected both with deposit, degeneration, and contraction; all probably the result of chronic excess of action. It is to be expected that modifications should arise in the degree and constancy of the morbid secretion, under such varieties of diseased appearance: but this is not, as yet, satisfactorily known; and I have certainly not always found the quantity of albumen increased in proportion to the apparent advance in the structural disease.

Another very important question is, the length of time which this disease may exist in the constitution, before it runs to its last fatal period: and although our experience in the hospital is great, the point of duration is yet undetermined; for, with all the advantages which an hospital affords for the multiplied accumulation of facts, there are some points on which the information derived in its wards is defective, and even apt to be erroneous; and amongst these may be reckoned one of great importance—the probable duration of life, under any disease. If a case is much relieved, the hospital physician loses sight of it, and in all probability sees it no more; knowing nothing of future relapses, or of the ultimate result. On the other hand, a very large proportion of his cases are arrived at the most advanced stages of the respective disorders: the circumstances of the patients have been such as to render them inattentive to the earlier indications of disease; and it is only when they can no longer pursue their laborious occupations that they are driven, too late, to seek relief. Hence the physician is liable to form a wrong estimate of the progress of the disease under more favourable circumstances; and it is necessary to correct his views by a comparison with the history and results of private practice.

There has not yet, perhaps, been sufficient time, since this disease of the kidneys first attracted attention, to say to what extent life may be prolonged while the body is under its influence; but I believe, with care, its fatal effects may be kept at bay, and a hazardous life may be protracted for many years. Should that care be neglected, the chance of life will be greatly diminished.—*Guy's Hospital Reports*, No. 2.

MORISON'S PILLS.

TRIAL FOR MANSLAUGHTER.

Central Criminal Court, April 6.

Before Mr. Justice Patteson.

Robert Salmon, a "Hygeian" agent, was put to the bar, charged with having caused the death of John M'Kenzie, by having administered to him, on the 20th of January, and at other times, large and excessive quantities of pills, composed of portions of gamboge, cream of tartar, and other articles of a noxious, destructive, and deleterious description, he having no knowledge of medicine, and having no license to sell or administer such medicine.

There were other counts in the indictment varying the charge against the prisoner.

Messrs. Clarkson and Bodkin appeared for the prosecution, and Sir F. Pollock,

and Messrs. Adolphus, C. Phillips, and Espinasse, conducted the defence.

Mr. CLARKSON stated the case to the jury, and called the following witnesses:—

Anne M'Kenzie, examined by Mr. BODKIN, deposed she was the widow of the deceased John M'Kenzie; he was 32 when he died. He was a man of good constitution. She knew a Miss Lane, who was doing needlework at her house in December last. She told witness she sold Morison's pills. Witness's husband was very much against them at first; but he said, towards the end of December, he would take them as an opening medicine; but at that time he never exceeded four; he had then no complaint. He said after taking them that they made him light. In January he had a rheumatic attack in the knee. In the latter end of December prisoner called at her house and asked for Captain M'Kenzie, her husband. He said he came from Miss Lane, and, putting down a card, said he lived at No. 6, Farringdon-street. He asked her what was the matter with her husband, and she said, nothing that she knew of. Her husband was then as stout healthy a man as could be seen in a day's walk. In a day or two the prisoner called, and saw her husband; she heard what passed. He told the deceased that he was not to take No. 2 pills without also taking the No. 1 pills. The prisoner said, "I am told you were much prejudiced against the pills at first, but they cure all diseases, and do a great deal of good." Her husband said he had bought an 11s. package at the "College of Health" to take out with him to the West Indies. Salmon went away, and did not call again until the middle of January, when her husband had a pain in his knee. Prisoner said he had seen Miss Lane, who had been informed by witness's little girl what was the matter with the deceased. She told him that Miss Lane ought not to have taken it upon her to send him, as they did not want him. In a few days the pain increased, and, by her husband's desire, Salmon was sent for. He came on Wednesday, January 20, and, before he went, ordered her to give deceased twenty of No. 1 of Morison's pills that night, and twenty of No. 2 on the following morning, "to drive off the No. 1's:" she gave her husband that night ten of the No. 1, and ten of the No. 2 on the following morning. Prisoner called in the early part of next day, and asked her if she had given him the proper number, and she said "yes." He told her that she was to increase five at every dose, which was to be administered night and morning. She did not tell him that she had administered only half the quantity he had ordered. Prisoner called every day but Saturday. She never gave deceased the full quantity ordered, but always a great deal less, and Salmon said he doubted her very much. She sometimes gave him fifteen or twenty at a time; sometimes none, at night; but she always gave him some in the morning. They affected his bowels very much, and frequently caused him to vomit. On the Sunday his bowels were much irritated, and he said he feared there was something the matter with him worse than his knee. Salmon called late on Monday. When she told him how deceased was affected, he said she had not been giving him doses enough, and had given him too much food. He said the fever would feed her husband without any food. Her husband was then so weak that he could hardly rise from his bed. Prisoner told her to give him hot water and salt, and ordered more pills, telling her to go on increasing each dose by five. He called on Tuesday, and on telling him that her husband was very ill, he said, she had not given him sufficient doses, and added, that she was alarming herself without any cause, and that if she would only give him the proper doses he would be well in a day or two. The purgative effect increased with the increase of pills, and on Tuesday night her husband became quite delirious. Mr. Cummings, a medical man, was called in on Wednesday. Salmon called twice on that day. The first call was after Mr. Cummings had left. Mr. Cummings had not administered any medicine to deceased on that day. Her husband was at the time quite delirious. Prisoner told her to give deceased twenty-five pills that night, as they would compose him to sleep, and he would be better in the morning. He called again about 10 o'clock at night. She was crying near the bed, and he said she had no cause of alarm, as her husband was doing well. She told him that a medical man had seen him, and said he was in a very dangerous state. He said, if he saw a medical man near the bed he would put him out of the house. He then administered twenty-five pills to the deceased, saying he doubted her. He told her to give him thirty or thirty-six of No. 2, in the morning. She did not do so, but gave him about twenty. They operated as a violent purgative, and frequently. He came on Thursday, and she told him, as she had always done, the state in which she conceived her husband to be, and he ordered more pills, and asked to see the pill-box. It was empty, her husband having taken the whole 11s. package, which had been purchased from Miss Lane. He said he would call upon Miss Lane, and order some more pills. She

said he was ordered not to take any more, and prisoner said he would give him 100 at a time if he thought he wanted them. She said her husband was getting very thin, and he replied, "I must take off the flesh before I can raise him up." He added, that the deceased would rise up a new man, and she said she should like to see him rise up the man he was before. He ordered her to give him 35 pills at three o'clock on that day. She told him that her husband could not take them, as he was continually throwing them up and throwing up blood also. He repeated his orders, and said he would have them sent. Miss Lane called about three o'clock, and brought a box of pills, which she said were "Morison's," and also a box of powders, for both of which witness paid 13s. 4d. Some brandy and water was offered to deceased, but he could not take it. Prisoner called next day about 10, and had two powders (about two table spoonfuls) in paper. He mixed them in some water: one was darker than the other. She asked him what it was, and he said it was pills pounded. He desired her to raise up her husband, which she did; he was then very weak, and could hardly move. (Here the witness became much affected). The prisoner then put the cup to the mouth of deceased, and he swallowed the contents. Prisoner went down stairs and saw a Mr. Gray. She went down also, but on her return up stairs she found the deceased had thrown up what he had taken, and a quantity of blood also. She sent for prisoner, who, on coming up, said, "As there is always straggling blood inside, don't alarm yourself." Her husband said, "My dear, it is poison—he has poisoned me." On prisoner going down stairs, Mr. Gray asked him if he was a medical gentleman, and he said "Yes." Mr. Gray asked to see his certificate, and prisoner said it was not usual for medical men to carry their diplomas about them. He asked him if he was enrolled as a surgeon, and he said he was. Mr. Gray said he was not treating Captain M'Kenzie properly, and asked him where he lived, to which he answered, "In the city," and went away. Mr. Gray then went for Mr. Cummings, the surgeon. Prisoner called again in the evening. Her husband had given orders not to let him see him, but he ultimately did go up stairs. Her husband said to prisoner, "Go out; you will be paid for your trouble, but you have poisoned me—you have poisoned me right out." She told prisoner that a doctor was to call next day, and he replied, her husband was doing well, and that she need not call in a doctor. She told him that one had been in already. To which he replied, "You are not so much to blame as your friends, who are alarming you needlessly." She expressed her own alarm, upon which the prisoner seemed himself much agitated and alarmed. He said he would call next day, and bring a medical man with him. A Captain Allen and Mr. Gray came in, and asked the prisoner a great many questions, and he always represented himself as a medical man. Deceased continued getting worse and worse. Prisoner called next day, and brought a Dr. Lynch, but she would not let them see her husband. This was on the Saturday. On that night, about 12 o'clock, her husband changed, and became cold all over; he continued getting worse until 3 o'clock on Monday morning, when he expired. He had received no medicine from the doctors.

Cross-examined by Sir F. Pollock.—She had never seen Salmon until he called upon her. At his first visit he gave her a card, stating his name and where he lived. He called three times before he attended as a professional gentleman. Her husband had, during that time, taken three or four doses of the pills, four at a time. She never gave her husband any pills made of bread. When Salmon ordered 20 pills night and morning, she gave only 10, but told him that she had administered the full quantity, upon which he more than once said they did not produce the effect he expected. She two or three times omitted to give any of the No. 1 pills at night, but not running. Prisoner said that the No. 1 were "searchers," and that No. 2 were to drive them off. The No. 1 pills did not purge the deceased. The largest number she had given him at a time was 20, except once, when she believed she gave him 25 of No. 1. She was afraid to give the full quantity, as she had heard of so many deaths by Morison's pills. She had known her husband all her life, they were school-fellows. He had been at sea since he was eight years of age. He never took any medicine but senna and Seidlitz powders. He had had a fever two years since in Jamaica, and had taken a good deal of mercury. He had never been attacked by rheumatism until the time when he sent for the prisoner.

Mr. Edward Spinks Cummings, surgeon and apothecary, residing at Limehouse, described the situation in which he found the deceased, in a manner which corroborated the testimony of the other witnesses as far as concerned him. He could scarcely breathe, and spoke with difficulty. He told witness how he had been treated, and complained of his knee, and of pains in the pit of the stomach. He examined the knee, and found that he

laboured under a rheumatic affection; that disorder had nothing to do with the disorder in the stomach. Having heard the sort of medicine he had been taking, he did not order it to be discontinued, as he had no charge which would authorize him to do so; but he gave it as his opinion that the treatment, if continued, would prove fatal. He advised chicken broth, in order to try and restore the tone of the stomach. When he called on the Friday, about eleven o'clock, he found him much worse. He lay still, with his eyes half closed; his pulse was weak, his breath faint, and it was witness's opinion that he would shortly die. Witness declined acting without assistance, and Dr. Cobb was in consequence called in; but deceased was not then in a condition to take medicine. An enema was administered to him. On Saturday night he became worse, and witness did not think that any medicine in the world would at that time relieve him. He understood that the pills consisted of portions of gamboge and aloes, and other ingredients. He had heard cream of tartar and asafœtida spoken of as other ingredients. There had been a post-mortem examination, and the stomach was found inflamed and ulcerated. There was at the bottom of the stomach, near the lower opening, a patch of ulceration larger than a shilling. If the deceased took the quantities of medicine described, it would account for the appearances he had witnessed, and which had caused death.

By the Court.—The ulceration must have been of recent occurrence; it could not have been of three months' standing. In his opinion it had commenced on the Friday. The appearance which he had found in the stomach would account for the death. Mucus such as he had seen, and in such quantities, would not have passed without some strong exciting cause.

Cross-examined by Sir F. Pollock.—He is a member of the College of Surgeons. He did not advise any medicines, as he thought they would be improper in the situation in which the deceased then was. He thought that the medicines named would, if mixed and administered in large quantities, produce the effects he had witnessed in the stomach. He thought twenty pills of gamboge and aloes would produce vomiting and purging. He had administered ten grains of aloes at a time, and three grains of gamboge at a time. When gamboge, aloes, cream of tartar, and asafœtida, were mixed, he could not tell the precise quantity at which the dose would cause danger to commence and safely to end. He should say that ten grains of Morison's pills, supposing them composed of aloes and gamboge, would be a strong dose; twenty would be dangerous, and, if taken night and morning, highly so; but much depended on the constitution. He did not know the difference between the pills No. 1 and No. 2; that which had most gamboge would be the strongest. If each pill contained half-a-grain of gamboge, with ten grains of aloes, it would be an over dose. He thought thirty of such pills, night and morning, for two or three days, would be an improper dose to take. If ten persons were to take such doses for several days together, at least two or three of them would die; and if it was stated by persons that they had taken such doses for a long time, either such statements must be false, or else witness's theory must be wrong. He never found that a small dose of aloes would cause irritation when a larger one would not. He had administered aloes in doses of from one to ten grains, and gamboge in doses of from one to three grains. He had heard Mrs. M'Kenzie's evidence to-day. He heard her say that she gave a less number of pills than was ordered, and that she sometimes kept back the pills No. 1 at night, and gave No. 2 pills in the morning. He also heard her say that No. 2 ought not to be taken without No. 1. He thought it would not be fair to judge of the effect of medicine so administered.

Re-examined.—He thought that a competent medical man could, on the Wednesday, have told that there was inflammation of the stomach, and would not have administered two spoonfuls of the pills powdered on the Thursday and Friday. Such a dose would produce the symptoms he witnessed in the stomach of the deceased, and was likely to cause death.

Dr. Frederick Cobb, examined by Mr. Bodkin.—Had been a practising physician in London 11 years, and was physician to the London Hospital. He saw the deceased on the Saturday before his death, and was informed that he had taken a large quantity of Morison's pills. Directed a mustard poultice to be applied to the pit of his stomach, and ordered a mucilage and some chicken broth to be given to him. The object of the mucilage was merely to sustain life, as no medicines were administered, though enemas of strong beef-soup, with small quantities of brandy, were given. Attended the *post mortem* examination of the body on Monday, the 1st of February, at 2 o'clock, and produces the notes of the observations he took as to the appearances 12 hours after death. The liver was rather large and congested, but no active disease; peritoneum free from inflammation or other disease; sto-

mach much contracted; the middle of the great curvature exceedingly inflamed, with two spots of ulceration, one the size of a shilling; the mucous membrane of the intestinal canal was inordinately injected with dark-coloured blood; in the ileum and jejunum the mucous membrane had the appearance of lymph effused within its substance, and greatly softened; in other parts the membrane was so thin as to give it the appearance of ulcerated destruction. In the cœcum and colon was a mass of yellow pulpy matter mixed with feculent matter. On opening the knee joint there was an effusion of lymph. The head was loaded, but not seriously diseased. There was abundant appearance in the stomach to account for death, but in no other part of the body. Taking large quantities of drastic medicine would produce such appearances. He had heard Mrs. M'Kenzie's evidence. He thought the dose described by her to have been administered to deceased on Friday, of two table spoonfuls of Morison's pills in powder, highly improper, and was of opinion no man of competent skill would have administered it. It required a nicety of judgment to discover the existence of inflammation, as it did in most internal diseases; but any person of competent skill seeing the deceased on Saturday must have known that he was labouring under some destructive mischief to a vital organ, and that in such case it was highly improper to continue the previous course of medicine. If the medicines of which he had heard had been administered in the quantities described, they would be quite sufficient to account for the death. He could name no medicine the good effects of which were increased in proportion to the increased quantity taken.

By the Court.—There was no medicine of which too large a dose might not be given. It was unfair to judge of the effects of medicine where the whole quantity prescribed was not administered. Telling Salmon under such circumstances that the full quantity had been taken would be likely to mislead him, and induce him to increase the dose, when he found that the effect he expected had not been produced.

Mr. R. Phillips, lecturer on chemistry at St. Thomas's Hospital, had analysed some of the pills in question. They were of different sizes and colours. No. 1 consisted of cream of tartar and aloes; there was a smaller quantity of another substance, the nature of which he had not time to ascertain; he at first thought it was colocynth. The larger, or No. 2 pill, consisted of aloes, gamboge, cream of tartar, and another substance, which he had not time to make out. He did not know the proportions of any of the medicines in either.

Mr. Thomas Springly Sandell, an assistant to last witness, said that both No. 1 and No. 2 contained a little asafœtida. He could not tell the proportions of any of the ingredients.

This closed the case for the prosecution.

The prisoner read a long written defence, vindicating the "Hygeian" system of one remedy for all diseases, and abusing the members of the faculty who apply various remedies to various complaints.

Several witnesses were called on behalf of the prisoner, or rather of Morison's pills. Some of them had taken 1000 pills in twenty days, without injury, and one man testified to having swallowed 20,000 pills in the course of two years, which cost him 22*l*.

Mr. Justice Patteson patiently summed up the evidence for the jury, who retired about ten o'clock, and in half an hour brought in a verdict of *Guilty*; they, however, recommended the prisoner to mercy, as he was not the compounder, but the vender only of the pills.

SCHOOL OF PHYSIC, DUBLIN.

To the Editor of the Medical Gazette.

Sir,

In reply to Dr. Macartney's letter, published in the Medical Gazette of the 19th instant, I beg leave to observe, that although extensive in its details, it disproves nothing in my statement. (See Med. Gaz. of 5th March.)

When the measure was originally adopted of printing a lengthy correspondence, the concise part of it, which connected the successive resolutions of the Board of Trinity College with one another, ought not to have been omitted, especially as its publication would have proved the consistency of their conduct, whilst its omission exposed them to the charge of caprice.

The superintendents of the School of Physic, vested by law with ample authority for its direction, are not in the habit of estimating the value of individual courses of lectures by the opinion that a Professor may entertain, either as to the importance of his own department, or the degree of his own merits; nor do they usually attend to his suggestions for the benefit of his colleagues. They consider that no nominal, and scarcely any real, advantage connected with an alteration, can

compensate for the inconveniences and abuses attendant on the delivery of two medical lectures at the same hour; and that no school of physic can be called "*complete*" where it is not in the power of the student to attend, during the session of his sojourning, two or even three courses of lectures on any subjects on which he may require information. Since surgery and the practice of medicine may, and very often do, form two of such subjects, they accordingly prohibit the delivery of lectures on both at the hour of three o'clock.

The Board of Trinity College know nothing of Drs. Macartney, Osborne, or Lendrick, in the transaction; but they are aware that it is desirable that the two lectures on the theory and practice of medicine should follow in immediate succession daily, in order to enable the students to attend during the same session, lectures on these almost inseparable subjects, without the necessity of going to such a distance as that of Sir P. Dun's Hospital (where these lectures are delivered) twice in the day; and further, that this object is unattainable without either requiring these *two* Professors to alter their present hours of lecture, as established for *many* years; or permitting two lectures at the same hour; or, finally, preventing the Professor of Anatomy and Surgery from lecturing at *three** o'clock. This they have done, and nothing more.

Besides the hour of one o'clock, allotted to the Professor of Anatomy and Surgery, I still maintain that there *are* others available for a second lecture in the day, if he chooses to deliver such.

1st. As to the objection to the "evening," urged by Dr. Macartney in the Gazette, page 1002—viz. "a low tavern, in which several students have been led into scandalous excesses even during the day"—such places of resort no doubt exist in the neighbourhood of the College *front and rear*, and, indeed, every where else; and persons of low habits and dissolute conduct will visit them, whether lectures are delivered in the evening or not; but from the experience of three years as a professor, and nine as a private lecturer, I can confidently assert, that a very little exertion on the part of the teacher to check immorality among his pupils, will be crowned with success, in the *few* instances where the disposition may display itself. If liable to be sometimes led astray by bad example, they are exceedingly manageable, where their preceptor steadily sets his face against all impropriety.

As to the other objection to "the night hour," it is sufficient to observe, as you will perceive from the reports in the Lancet, that Sir Astley Cooper shewed both preparations, and operations on the dead body, to his surgical class in the evening.

2d. As to "the morning hours" being unfit for surgical lectures, on account of the students being engaged at "hospitals" (unconnected with the School of Physic), it is by no means necessary that Dr. Macartney's pupil should visit, among many hospitals, that where the hour of attendance is the one selected for *his* surgical lecture; nor is it very consistent in Dr. M. to object to interfere with the hour of a foreign establishment, and yet to encroach on that which has for years been occupied in the School of Physic with which he is connected.

Whilst noticing *my* "interest," Dr. M. has omitted to allude to his own, as affected by the increase of emolument from the separation of his courses, and the transfer of that on surgery to the hour of three o'clock. That such a practice was lucrative I take for granted, from his assertion in the 1002d page of the Gazette, that on discontinuing it, he "returned money" to the class.

I feel obliged by his acquitting me of "any wish to injure the school." Neither he, I, nor any other Professor, however, have the power, if we even had the inclination. Its management is vested in those who have the means of controlling us, and who will doubtless take care that we adhere to the terms of our oath, and that the establishment shall be conducted in the manner most conducive to the continuance of its prosperity, and to the welfare of its pupils.—I remain, sir,

Your very obedient servant,
CHARLES LENDRICK.

Dublin, March 24, 1836.

* The lectures on the practice and the theory of medicine occupy the two hours (from three till five) preceding that of the College dinner.

REMUNERATION FOR ATTENDANCE AT INQUESTS.

To the Editor of the Medical Gazette.

SIR,

I WILL thank you to publish a copy of the following petition, which I have sent to Lord Ashley, one of our county members, to present in the House of Commons, in an early number of the Medical Gazette.

I remain, sir,
Your obedient servant,
JOHN REYNOLDS ROWE,
Secretary to the County of Dorset Medical Association.

Wimborne, March 31, 1836.

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament assembled.

The humble petition of the members of the Medical Association of the County of Dorset,

Sheweth,

That medical practitioners are occasionally summoned by his Majesty's coroners to give evidence in cases of inquest.

That in order to afford such evidence, it is often necessary to make post-mortem examinations, requiring much time, trouble, and skill, and attended with danger to the health and even life of the operator.

It has long been a subject of grievance to medical practitioners, that for this duty the law awards no compensation, and they are disappointed by finding that the Poor-Law Amendment Act provides no remedy.

Considering the importance of the services thus rendered to society at large, especially in the furtherance of the ends of justice, it does appear just that the same reasonable compensation which is awarded to all other professional men for public duties should be extended to medical practitioners.

We, the undersigned, the committee of the said Association, humbly pray that your honourable House will be pleased to take this matter into your early consideration, and provide such redress as shall be deemed equitable.

And your petitioners will ever pray.

COLLEGE OF SURGEONS.

LIST OF GENTLEMEN WHO RECEIVED DIPLOMAS IN MARCH.

Thomas Dakyn, A.
Edward H. Eykyn, Ackleton, Salop.
Thomas Bentley, Roundwood, Wicklow.

LECTURES ON MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

By Jon. Pereira, Esq., F.L.S.

Lecture XXIX.

There yet remain some salts of potash for examination; and the next one which I propose to notice is the

Chlorate of Potash.

History and synonymes.—This salt (called also *oxymuriate*, or *hyperoxymuriate of potash*) was first prepared by Higgins, who seems to have confounded it with saltpetre; but in 1786, Berthollet distinguished them.

Preparation.—It is prepared by passing chlorine gas into a solution of subcarbonate of potash. The carbonic acid is expelled, while part of the alkali is decomposed; its metallic basis, uniting with chlorine, forms chloride of potassium, and its oxygen, combining with chlorine, forms chloric acid, which, with some undecomposed potash, forms chlorate of potash; which is separated from the chloride by its less solubility.

Re-agents.	Results.
$6\ \dot{K}\ \ddot{C}$	$6\ \ddot{C}$
$6\ Chl$	$5\ K\ Chl$
	$\dot{K}\ \overset{\therefore\cdot\cdot}{Chl}$

Berzelius gives a somewhat different explanation of the process, but I must refer those who wish for an account of it, to his work.

Properties. — It crystallises in pearly rhomboidal plates, the primary form of which is an oblique rhombic prism. Its taste is cool, and somewhat similar to nitre. At 32°, 100 parts of water dissolve only 3·3 parts of this salt.

Composition.—It is anhydrous, and consists of—

1 atom chloric acid	76
1 atom potash..........	48
	124

Impurity.—Chloride of potassium may be readily detected by adding a solution of nitrate of silver, which produces no visible change with a solution of the pure salt, but a white precipitate of chloride of silver, with any chloride of potassium that may be present.

Characteristic tests.—This salt is known to be a chlorate by the following characters:—when heated, it fuses, gives out oxygen, and is converted into chloride of potassium; if thrown on a red-hot coal, it deflagrates—a property, however, common to several other salts. Sulphuric acid gives it an orange red colour, evolves the peroxide of chlorine, known by its yellow colour, and great explosive power when heated. Rubbed with sulphur or phosphorus, it explodes violently. The base of the salt is known by the tests for potash, already mentioned.

Physiological effects.—Every atom of this salt contains six atoms of oxygen. Now, as it readily gives out this gas, if heated, it has been assumed, that when swallowed, the hydrogen and carbon of the system would deprive the chlorate of this principle; and, therefore, in various diseases, supposed to be curable by oxygen, this salt has been employed. But it has not been proved that oxygen is evolved in the system: for Wohler and Stehberger, in their account of the action of various diuretics, assert, that the chlorate passes off by the urine unchanged. In this respect, then, it is like the nitrate, which also contains six atoms of oxygen. Other

effects ascribed to the chlorate are not supported by strict observation. Thus, in 1818, Duchâteau stated, that eighteen grains, taken at thrice, caused convulsions, followed by delirium; but as these effects have not resulted, in other cases, from much larger doses, we cannot help suspecting some error. Diuresis is another effect ascribed to this preparation, and I believe justly. On the whole, this salt seems to operate in an analogous manner to the nitrate of potash.

Uses.—Chlorate of potash owes its introduction into use as a medicine, to hypothetical considerations. The beneficial effects of mercurials, in the venereal disease and liver complaints, were at one time supposed to depend on the oxygen which these preparations communicated to the system; and hence, substances containing a large quantity of this principle, as nitric acid and the chlorate, were regarded as valuable substitutes. Some diseases were supposed to arise from, or be connected with, a deficiency of oxygen in the system—for example, scorbutus and malignant cholera: here the chlorate, as an agent communicating oxygen, was thought to be indicated. In other cases, this medicine was employed on account of the presumed tonic effects of the evolved oxygen. In these, as well as in other instances which I might bring forward, chlorate of potash has been administered on erroneous principles, and, in most cases, with little advantage; and we have yet to learn its proper effects and uses.

Dose.— From fifteen grains to half a drachm.

Vegetable Salts of Potash.

Under this denomination I include those potash salts which contain a vegetable acid. Those employed in medicine are, the *acetate*, the *tartrate*, the *bitartrate*, and the *citrate*. They act very mildly, and, when taken into the stomach, appear to undergo partial digestion—for their acid is converted into the carbonic acid; and, after their use, the urine is rendered alkaline, and contains the carbonate of potash. Now this is a point of great practical importance,—for, in the first place, in that form of lithiasis attended with a deposit of lithic acid in the urine, instead of giving either a caustic or carbonated alkali, we may exhibit a much more agreeable and pleasant compound—I mean, the common effervescing draught, knowing that this will as effectually render the urine alkaline, as the caustic or carbonated alkali. But, in the second place, in the treatment of phosphatic deposits, these salts are to be carefully avoided; so that, although the patient may take, with benefit, bottled soda water (that is, an aqueous solution of carbonic acid), the soda powders (composed of tartaric acid and carbonate of soda) may not only be inefficacious, but absolutely hurtful. Alluding to the phosphatic deposits, Dr. Prout says, "were I required to name the remedy calculated to do the most mischief, I should name the common saline draught, formed of potash or soda, and *some vegetable acid.*"

1. *Acetate of Potash.*

History and synonymes.—It appears to have been first clearly described by Raymond Lully, in the thirteenth century, and has been known by several appellations, such as *terra foliata tartari, diuretic salt*, &c.

Native state.—Geiger, in his "*Handbuch der Pharmacie*," says this salt is found in some mineral springs; but I much doubt the accuracy of the statement. It probably exists in several plants, which, by incineration, furnish the carbonate of potash. The sap of the elm, Winter's bark, linseed, senna leaves, the rhizome of ginger, and various other vegetable matters, are said to contain it.

Preparation.—It is prepared by adding carbonate of potash (subcarbonate of the shops) to acetic acid obtained by the distillation of wood. The acid unites with the potash, and disengages carbonic acid. The liquid is to be evaporated, until a pellicle appears on the surface, so that when cold it may concrete.

Properties.—It is usually met with as a white solid, with a foliated texture, odourless, but having a pungent saline taste, and a soapy feel. It is exceedingly deliquescent, and, therefore, ought to be preserved in a well stoppered bottle. It is very soluble both in water and alcohol; indeed, in water, it is one of the most soluble salts we are acquainted with. At 60°, 100 parts of the salt will dissolve in 102 parts of water. When heated, it fuses and is decomposed into *pyroacetic spirit*, and *carbonate of potash*. One atom of this spirit contains the elements of acetic acid, minus those of carbonic acid.

Composition.—According to Dr. Thomson, this salt consists of—

1 atom acetic acid	51
1 atom potash	48
2 atoms water	18
	117

Purity.—It frequently re-acts as an alkali, owing to a little excess of potash. It should be perfectly colourless.

Characteristic tests.—As an acetate, it is known by its great solubility, and by the odour of acetic acid, evolved on the addition of strong sulphuric acid.

Physiological effects.—Swallowed in doses of two or three drachms, it causes purg-

ing, sometimes accompanied with griping. When taken in smaller doses, more especially if largely diluted, it acts as a diuretic, and slightly as a diaphoretic. In its passage to the kidneys it becomes decomposed, and converted into the carbonate of potash, which may be detected in the urine. Probably the pulmonary excretions of those who employ it also become impregnated with this salt, since it has been said that in persons with delicate lungs it acts as an irritant.

Uses.—In this country it is rarely employed, except as a diuretic in dropsical complaints. On the continent, however, it is administered in various other diseases, such as scirrhus of the pylorus, chlorosis, and visceral and glandular enlargements.

Administration.—It is given as a diuretic in doses of from a scruple to a drachm and a half, dissolved in some mild diluent. In larger doses, as already mentioned, it acts as a purgative.

2. *Bitartrate of Potash.*

History and synonymes.—In its impure form, as a deposit from wine, it must have been known at a very early period. "It is called *tartar*," says Paracelsus, "because it produces oil, water, tincture, and salt, which burn the patient as *hell* does." Scheele, in 1769, first explained its nature. Its synonymes are *cream of tartar, supertartrate of potash*, and *acidulous tartrate of potash.*

Native state.—It is a constituent of vegetables: thus it is found in grapes, tamarinds, cetraria islandica, and many other plants.

Production.—All the bitartrate of commerce is obtained during the fermentation of wine. It exists, as I have just mentioned, in grapes; but being insoluble, or nearly so, in water mixed with alcohol, it deposits during the fermentation of the juice of the grape—that is, when alcohol is produced; and it forms a crust on the sides of the casks, known in commerce under the name of *crude tartar (tartarus crudus)*, or *argol*, and which is termed *white* or *red (tartarus albus vel tartarus ruber)*, according as it is obtained from white or red wine.

Argol, or *crude tartar*, occurs in crystalline cakes of a reddish colour, and is composed of the bitartrate of potash, tartrate of lime (and sometimes racemate of potash), colouring and extractive matter, &c.

At Montpellier, bitartrate of potash is procured thus:—The argol is boiled in water, and the solution allowed to cool, by which a deposit of crystals is obtained; these are washed with cold water, and dissolved in boiling water, containing charcoal and alumina (clay); the latter substances being employed to remove the colouring matter with which they precipitate. The clear liquor is allowed to cool slowly, by which crystals of the bitartrate are formed.

Properties.—As met with in commerce, this salt forms a white crystalline mass, without odour, but having an acidulous and gritty taste. When carefully crystallized, the form of the crystals is a triangular prism, having dihedral summits, the primary form being a right rhombic prism. It is unaltered by exposure to the air; but when heated decomposes, swells up, various volatile products are evolved, and charcoal and carbonate of potash left behind, forming *black flux*. It is slightly soluble only in water. Thus at 60°, one part of this salt requires 234·6 of water to dissolve it. The solution decomposes by keeping.

Composition.—In the crystalline state it consists of

2 atoms tartaric acid (67×2) ····	134
1 atom potash ················	48
1 atom water ················	9
	191

Characteristic tests. — When heated, it swells up, gives out inflammable gases, evolves an odour analogous to caromel (burnt sugar), and gives, as a residue, charcoal and carbonate of potash; which latter, by solution in water, may be recognized as a potash salt by the tests before mentioned. Another character of this salt is its slight solubility in water—the solution reddening litmus. The addition of caustic potash to the water increases the solubility of the salt, whereas alcohol diminishes it. Acetate of lead added to a solution of the bitartrate, forms a copious white precipitate; lime water has the same effect. Mixed with alkaline carbonates, this salt causes effervescence. Boracic acid, or borax, very much increases the solubility of this salt in water, forming what has been termed *soluble cream of tartar.*

Impurity.—The bitartrate of commerce usually contains 5 or 6 per cent. of tartrate of lime. This, however, is of no practical importance.

It is sometimes adulterated with *sal enixum*, or the bisulphate of potash. This is easily detected, by dissolving a little of the suspected salt in water, and adding a solution of chloride of barium; which occasions a white precipitate of the sulphate of barytes, insoluble in nitric acid.

Physiological effects.—In large doses (as half an ounce) it acts as a cooling purgative, causing watery evacuations: hence it is termed a hydragogue. Like most of the vegetable acid purgatives, it is very

apt to excite flatulence and griping, and, by continued use, to disorder the digestive functions, and thereby to give rise to emaciation from imperfect nutrition. When taken in smaller quantities, and dissolved in water, it allays thirst, diminishes febrile heat, and increases the secretion of urine.

Uses.—On account of its gritty quality, it is employed as a tooth-powder. Various formulæ for dentrifices will be found in Jourdan's "*Pharmacopée Universelle;*" but I may state that a very good tooth-powder is made of equal parts of cream of tartar, powdered rhatany root, and myrrh.

As a purgative, the bitartrate is rarely employed alone. A mixture of about ten grains of jalap, and a scruple or half a drachm of cream of tartar, may be administered with advantage in dropsical affections. An electuary composed of this salt, sublimed sulphur, and confection of senna, is frequently used in skin diseases, in affections of the rectum (as piles, stricture, and prolapsus), in liver complaints, dropsy, &c. The *compound senna powder* of the London Pharmacopœia contains this salt, mixed with senna, scammony, and ginger: in doses of half a drachm, it is a useful cathartic. An effervescing aperient may be prepared by mixing 3 drachms of the bitartrate with $2\frac{1}{2}$ drachms of the carbonate of soda (the subcarbonate of the shops): the resulting salt is the tartarized soda.

Cream of tartar is most useful, as a refrigerant and diuretic, taken in solution, in the form either of imperial or cream of tartar whey. *Imperial* is formed by adding boiling water to cream of tartar, and flavouring with lemon-peel and sugar. *Cream of tartar whey* is made by adding about two drachms of cream of tartar to a pint of boiling milk, and, when cold, separating the curd by a strainer. Imperial is an exceedingly useful refrigerant drink in febrile complaints. The whey may be diluted with warm water, and taken in dropsical complaints. Some have proposed to add borax to cream of tartar, with the view of increasing the solubility of the latter salt; but no therapeutica. advantage is thereby obtained.

Dose.—As a purgative, this salt may be given in doses of from four to eight drachms; as a diuretic, from a scruple to a drachm.

3. *Tartrate of Potash.*

History and synonymes.—This salt was known to Lemery. It has been termed *tartarized tartar, tartarized kali, soluble tartar,* or *vegetable salt.*

Preparations.—It is readily prepared by saturating the bitartrate with the subcarbonate of potash.

Properties.—It is usually met with in the shops, in a granular state, but it may be crystallized; the primary form of the crystals being a right oblique angled prism. Its taste is saline, and somewhat bitter. It deliquesces when exposed to the air, and is soluble in its own weight of water at 50°; the solution decomposes by keeping.

Composition.—It consists of

1 atom tartaric acid	67
1 atom potash	48
	115

Characteristics.—When heated to redness, it is decomposed, leaving as a residue charcoal and carbonate of potash. A solution of the tartrate produces a white precipitate with a solution of sugar of lead,—also with lime water; the precipitates being dissolved by free tartaric acid. When heated, the salt evolves the odour of caromel. If an excess of any strong acid (as the sulphuric) be added to a solution of this salt, we obtain crystals of the bitartrate. The tartrate is readily distinguished from the bitartrate by its deliquescent property, its greater solubility, and its want of acidity.

Impurity.—It may contain excess of acid or base, either of which is easily recognized—the one by litmus, the other by turmeric.

Incompatibles.—Acids added to this salt, by abstracting part of the potash, cause the precipitation of the bitartrate. Tamarinds have the same effect.

Physiological effects.—This salt is a gentle purgative, analogous in its action to the sulphate of potash; from which it differs in being milder in its operation, and partially digestible; for, like the other vegetable salts of the alkalies, it is decomposed in the system, and converted into the carbonate of potash, in which state it is found in the urine.

It is said to have the power of preventing the griping of other more active cathartics—as senna and scammony; but, from my own personal observations, I doubt the correctness of this statement.

Use.—It is employed as a mild purgative in dyspepsia, at the commencement of diarrhœa, in some liver complaints, &c. Sometimes it is used as an adjunct to other more active purgatives: as the infusion of senna.

Dose.—It may be given in doses of from two or three drachms to half an ounce, or even an ounce.

4. *Citrate of Potash.*

Preparation.—This salt is not kept prepared. It is easily made when wanted

by mixing either citric acid or lemon-juice with the carbonate or bicarbonate of potash.

In the shops, a preparation called *lemon and kali* is kept, composed of sugar, dry citric acid, and dry bicarbonate of potash, but it is necessary to keep it in a well-stoppered bottle, since it abstracts water from the atmosphere.

The following are the proportions for making extemporaneously the citrate of potash:—

18 grains of citric acid .... ½ fluid ounce of lemon juice	saturate ℈j. of the subcarbonate of potash.
15 grains of citric acid .... 3½ fluid drachms of lemon juice	saturate ℈j. of the carbonate of potash.

Effects and uses.—The citrate is the mildest of all the alkaline salts. Taken in an effervescing condition, it is an excellent means of diminishing irritable conditions of the stomach. It promotes very slightly the secretions of the alimentary canal, the cutaneous transpiration, and the renal secretion; and, like other vegetable salts of potash, renders the urine alkaline.

Iodide of Potassium.

This salt, usually known in commerce as the *hydriodate of potash*, has been already spoken of, under the head of iodine.

The Sulphated Tersulphuret of Potassium.

History and synonymes.—Geber was acquainted with the solubility of sulphur in an alkaline solution; but Albertus Magnus taught the method of procuring sulphuret of potassium by fusion. The preparation kept in the shops is a mixture of the tersulphuret of potassium and sulphate of potash, and is called in the Pharmacopœia *sulphuret of potash*, and sometimes *liver of sulphur*.

Preparation.—One ounce of sulphur is fused with two ounces of subcarbonate (that is, the carbonate) of potash, in a covered crucible.

Theory.—The re-acting proportions are 10 atoms of sulphur and 4 atoms of the anhydrous subcarbonate. One atom of sulphur abstracts three of oxygen from three of potash, and forms one of sulphuric acid; which, with one of potash, produces one of sulphate of potash. Four atoms of carbonic acid escape: nine atoms of sulphur unite with the three of the potassium of the decomposed potash, and form three atoms of the tersulphuret of potassium. About 12½ per cent. of the subcarbonate is usually left undecomposed. If the heat employed be sufficient to decompose the whole of the subcarbonate, we then obtain a mixture of sulphate of potash and bisulphuret of potassium.

Re-agents.	Results.
10 S	$4\ddot{C}$
$4\dot{K}\ddot{C}$	3 (K + 3 S)
	$\dot{K}\dddot{S}$

Properties.—When fresh prepared, it has a liver-brown colour; and hence its name *hepar sulphuris.* Its taste is acrid, bitter, and alkaline. If quite dry it is inodorous, but when moistened it acquires the odour of sulphuretted hydrogen. Exposed to the air, it undergoes decomposition, from the action, not only of the aqueous vapour, but also of the oxygen. It becomes green and moist, and ultimately whitish. This change depends on the absorption of oxygen; so that two atoms of sulphur are deposited, while one atom of sulphur with one of potash form hyposulphite of potash: this becomes sulphite, and ultimately sulphate of potash, by the absorption of more oxygen. Sulphuret of potassium is soluble in water.

Composition.—If prepared according to the directions of the Pharmacopœia, this compound will consist of

3 atoms of tersulphuret of potassium	252
1 atom of sulphate of potash....	88
Carbonate of potash	31·5
	371·5

Characteristic tests. — Hydrochloric acid added to it, causes the evolution of sulphuretted gas: the solution of the sulphuret in water produces a black precipitate, with the solutions of lead, silver, bismuth, copper, &c. That it contains potassium may be determined thus:—Add excess of hydrochloric acid to a solution of it; boil, and filter. The before-mentioned tests for potash may be then applied.

Physiological effects.—In *large doses* this substance is an energetic poison; three drachms having proved fatal in the human subject within fifteen minutes. Locally it acts as a powerful irritant, and when swallowed produces an acrid taste, burning pain and constriction in the thoat, gullet, and stomach; vomiting and purging. But the nervous system also becomes affected, as is proved by the faintness, the almost imperceptible pulse—by the convulsions, and in some cases by sopor,—symptoms somewhat similar to those caused by sulphuretted hydrogen: in fact, this gas is copiously developed in the stomach. When administered in *small*

or *therapeutical* doses (as from six to ten grains) it acts as a general stimulant, increasing the frequency of the pulse, augmenting the heat of the body, promoting the different secretions, more especially from the mucous membranes; and sometimes exciting local irritation, marked by pain, vomiting, and purging.

Uses.—Externally it is dissolved in water, and used as a bath in chronic skin diseases, such as scabies, eczema, lepra, &c. For this purpose four ounces of the sulphuret will be sufficient for thirty gallons of the water. These baths are said to be particularly useful in the treatment of scabies in children. However, Rayer states that 20 baths are required to accomplish the cure. According to the same writer, in order that these baths should be successful, the patients should remain several hours in them, which, of course, is an objection to their use. Lotions in skin diseases are sometimes employed, containing a much larger quantity of the sulphuret.

Internally,—this salt has been administered for various purposes. Thus 5 or 6 grains dissolved in a pint of water have been used as a drink in cutaneous diseases. There are also many other maladies in which its employment has been advised; for example, Senf has lately recommended it as a substitute for calomel in those inflammations attended with lymphatic exudation, such as croup. Rheumatism, gout, affections of the glandular system, pulmonary disorders, are other cases in which it has been advised. It has been proposed as an antidote in cases of poisoning by arsenic, lead, copper, corrosive sublimate, &c.; and though it is not perhaps to be denied that in some instances the new compounds formed might be less poisonous than the old ones, yet the practice ought not to be followed, since the proposed antidote is itself a powerful poison.

Administration.—I have already spoken of the principal methods of using it. When taken internally, it may be given in doses of from 3 to 10 grains.

Antidotes.—In the event of any accident happening with this substance, the antidote for it is a solution of chloride of soda, or of chloride of lime.

SODIUM.

General Remarks. — This metal (called also *Natrium*, hence its symbol N), was discovered in 1807, by Sir Humphry Davy. It is procured from soda by precisely the same methods that potassium is obtained from potash. It agrees with potassium in several of its properties: thus, it is lighter than water (its specific gravity being 0·972 at 60°), and when thrown on water rolls about rapidly and decomposes this fluid, but it seldom takes fire, in which circumstance it differs from potassium; and when it does inflame, it burns with a yellow (not red, as potassium) coloured flame. By its action on water it becomes oxidized, and forms soda, which is left in solution.

Native state.—Sodium is met with in both kingdoms of nature. The chloride occurs in immense masses in the mineral kingdom: carbonate, borate, sulphate, and silicate of potash, occur either alone, or combined with other substances. It is met with in both vegetables and animals. But potassium is found in larger quantity than sodium in plants; and the reverse holds good with respect to animals, in which sodium preponderates.

Pharmacological compounds of sodium.—I shall briefly notice the following compounds of sodium.

1. The *protoxide of sodium*, (soda) and some of the *oxysalts* of soda.

2. *Chloride of sodium.*

Soda.

Synonymes.—The alkali, called also *natron*, is sometimes termed *mineral alkali*, in opposition to potash, which is called the vegetable alkali.

Preparation.—Caustic soda is procured from the carbonate by precisely the same process that caustic potash is obtained from the carbonate of potash.

Composition.—Soda in the pure anhydrous state consists of

1 atom sodium	24
1 atom oxygen	8
	32

Characteristic tests for soda and its salts.—The ferrocyanurets and hydrosulphurets occasion no precipitates. From the alkaline earths soda and its salts are distinguished, by not precipitating the carbonate of potash or of soda. From potash and its salts those of soda are distinguished by not being precipitated by tartaric or perchloric acids, nor by the chloride of platinum. Further, it is distinguished from both potash and lithia, by communicating a yellow tinge to the flame of alcohol.

The *physiological effects and uses* are precisely similar to those of potash, already fully described. Fourcroy thought that, as soda is contained in animals in larger quantity than potash, it was a better agent for medicinal use. This notion, which indeed is very plausible, does not appear to be supported by experience; for Sir Gilbert Blane, Mr. Brande, and others, assert they have obtained beneficial effects from the use of potash in calculous diseases, where soda has failed to give relief. Indeed, Sir Gilbert Blane has endeavoured to account for it, by supposing that the soda becomes

applied to the purposes of the economy before it reaches the kidneys, whereas the potash is carried to these organs with a view of being thrown out of the system.

Carbonates of Soda.

Three carbonates of soda are described, but only two are employed in medicine, namely, the carbonate (or mono-carbonate) and the sesqui-carbonate.

1. *Mono-carbonate.*

History and synonymes.—This salt has been known for a long period; sometimes being called *mild mineral alkali*, or *aerated mineral alkali*, or the *subcarbonate of soda*, the name by which it is at present designated in the London Pharmacopœia.

Native state.—It is found native at Delrezin, in Hungary, and Montenuovo, near Naples.

Preparation.—It may be prepared from *barilla*, from *kelp*, or from *common salt* (that is, chloride of sodium).

(*a.*) *From barilla.*—The substance called *barilla* is an ash obtained by the combustion of plants, principally belonging to the family *chenopodeæ*. They grow in the neighbourhood of the sea, and, according to Chevreul, contain the oxalate of soda, which, by combustion, is converted into the carbonate. *Alicant barilla* is said by Lagasca, in his Memoir on the *barilleras* of Spain, to be obtained from the *salsola sativa, chenopodium setigerum*, and some other species. *Narbonne barilla* is got from the genus *salicornia* (especially the species called *herbacea*). For the production of barilla the plants are cultivated, when ripe, cut, and dried in heaps, and then burned in holes in the ground. The fused ash constitutes the barilla. It is a hard, greyish or blueish mass, not deliquescent, having an alkaline acrid taste, and peculiar odour, and composed of carbonate and sulphate of soda, sulphuret and chloride of sodium, carbonate of lime, alumina, silicic acid, oxide of iron, and charcoal. The quantity of carbonate of soda varies: Alicant barilla contains from 25 to 40 per cent.

By boiling a pound of barilla (*soda impura* of the Pharmacopœia) in 4 pints of distilled water, filtering, evaporating, and crystallizing, we obtain the *sodæ subcarbonas* of the London Pharmacopœia.

(*b.*) *From kelp.*—When speaking of iodine, I alluded to the manufacture of *kelp*. This substance is obtained by the combustion of some of the *algæ*; the most valuable species for this purpose being *fucus vesiculosus, nodosus*, and *serratus, laminaria digitata* and *bulbosa, himanthalia lorea*, and *chorda filum*. In these plants the soda exists as the oxalate, and by combustion is converted into the carbonate. In the year 1830, Dr. Greville mentioned in his "*Algæ Britannica*," that probably 20,000 people were occupied with the manufacture of kelp in the Orkney Islands alone. At one time it fetched 22*l*. per ton, but now (that is, 1830), hardly 5 guineas can be obtained for it.

The constituents of kelp I have already mentioned *. The quantity of carbonate of soda which it contains is much inferior to that found in barilla.

Kelp is now of little value as a source of soda, being principally used for the production of iodine.

(*c.*) *From chloride of sodium.*—Of late years a large proportion of the soda of commerce is procured by the decomposition of sulphate of soda; and the resulting salt is denominated *artificial soda*. The process adopted varies in some of its details in different manufactories; but the following sketch will give you some idea of it. Sulphuric acid is added to common salt, by which sulphate of soda is obtained, while the hydrochloric acid gas is allowed to escape, not being worth the expense of collection. The sulphate of soda thus formed is mixed with small coal, (sawdust being too expensive) and heated in a reverberatory furnace. By this means the sulphate is deprived of its oxygen by the carbonaceous matter, and converted into sulphuret of sodium, which is roasted by a coal fire, and thereby converted into carbonate of soda, the sulphur being burned off.

In other instances, the sulphate of soda is decomposed by a mixture of chalk (carbonate of lime) and small coal, in a reverberatory furnace. The results vary with the proportion of the ingredients employed. At a large manufactory at Brentford, which I lately inspected, the proportions were nearly 2 parts sulphate, 1 part chalk, and 1 part coal. Now we can account for the products of the operation, by supposing that in the first place the heat causes a mutual re-action between the sulphate of soda and carbonate of lime, by which we obtain sulphate of lime and carbonate of soda: and that the coal decomposes the sulphate of lime, converting it into sulphuret of calcium. The mass resulting from this operation has a greyish appearance, somewhat similar to barilla, and is termed *English barilla*, or the *ball alkali*.

This is dissolved in water, by which the sulphuret of calcium and carbonate of soda, re-acting on each other, generate carbonate of lime and sulphuret of sodium. There is also in the solution (which is of a greenish colour) carbonate and sulphate of soda. The solution is evaporated to dryness, forming a dark or blackish mass, which is

* Lecture 224, Medical Gazette, vol. xvii. p. 834.

roasted in a furnace so as to convert the sulphuret of sodium into carbonate of soda. The resulting mass is dissolved in water, and crystallized in open iron pans.

In the northern parts of Great Britain, the manufacture of this substance is conducted on a most extensive scale: the manufacturers make their own sulphuric acid, which they employ to convert the common salt into sulphate of soda, from which they manufacture the carbonate. The muriatic acid fumes are allowed to escape to the great destruction of the surrounding vegetation, as I have already mentioned when speaking of hydrochloric acid.

Properties of carbonate of soda.—It is a crystalline solid, having a mild alkaline taste, and reacting as an alkali on turmeric and other vegetable colours. When exposed to the air it effloresces. Heated, it melts in its own water of crystallization, boils up, and becomes ultimately anhydrous.

Composition. — Crystallized carbonate of soda is liable to variation on two points—the quantity of water it contains, and the form of the crystal; the latter probably depending on the former. Dr. Thomson mentions four carbonates, containing respectively 1, $1\frac{1}{2}$, 8, and 10 atoms, of water. The Pharmacopœial salt, however, consists of—

1 atom carbonic acid	22
1 atom soda	32
10 atoms water	90
	144

And the primary form of its crystal is said by Mr. Brooke to be the oblique rhombic prism.

Adulteration. — Sulphate of soda, and chloride of sodium, are sometimes found in the subcarbonate of soda of commerce. The first is known by the addition of chloride of barium, which produces a white precipitate insoluble in nitric acid. If a chloride be present the nitrate of silver causes a white precipitate, insoluble in nitric acid, but soluble in ammonia.

Characteristic tests.—The means of proving the salt is a carbonate are the same as those employed for carbonate of potash, from which salt the carbonate of soda is distinguished by the tests for soda already detailed.

Physiological effects.—These are similar to the effects of the carbonate of potash; and as the carbonated alkalies act in an analogous (though milder) manner to the caustic alkalies, it would be work of supererogation to go over this subject again, after the remarks made when speaking of caustic potash.

Uses.—These are similar to the uses of carbonate of potash; however, you will recollect the probable greater efficacy of potash (caustic solution, or subcarbonate) than soda, in lithiasis. In some cases the carbonate of soda is preferred to the carbonate of potash, as being less deliquescent.

Administration.—The carbonate of soda may be given in powder or solution, in doses of from gr. x. to ℈j. If employed in the effervescing draught, the proportions required to saturate acids are as follows:—

15 grains of citric acid .... }
℥iijss. of lemon juice .... } will saturate $28\frac{4}{5}$ grains of the carbonate of soda.
15 grains tartaric acid .... }

If you wish to give this salt in pills, you must deprive it of its water of crystallization, as in the preparation called in the Pharmacopœia *sodæ subcarbonas exsiccata*; 54 grains of the anhydrous salt being equal to 144 of the crystals.

Sesquicarbonate of Soda.

History and synonymes. — Native sesquicarbonate of soda was formerly called *νίτρον*, and *nitrum*, and was confounded by the ancients with saltpetre.

Native state.—Under the name of *trona*, or *natron*, this salt is found abundantly in the province of Suckena, belonging to Tripoli. The walls of Cassar, an African fort, now in ruins, were said to have been built of it. The substance called *urao*, which occurs at the bottom of a lake, a day's journey from Merida, in South America, appears also to be this substance.

Preparation.—Under the name of carbonate of soda, a powder is sold in the shops for the manufacture of *soda powders*, which is a sesquicarbonate, and is prepared by dissolving six parts of the subcarbonate of soda, and four parts of the carbonate (or rather sesquicarbonate) of ammonia, in four parts of water, and evaporating until a pellicle forms.

Properties.—It is usually obtained in a pulverulent form; but Dr. T. Thomson states it may be obtained in crystals. It has a feebly alkaline taste, and is less soluble in water than the subcarbonate.

Composition.—It consists of—

$1\frac{1}{2}$ atoms carbonic acid	33
1 atom soda	32
2 atoms water	18
	83

Physiological effects.—Its effects are analogous to the other carbonates of soda, or to the carbonates of potash. Of course it

i less powerful in its local action than the simple carbonates.

Uses.—It is used in preference to the subcarbonate on account of the larger quantity of carbonic acid which it contains, and by which, therefore, it excites mere effervescence. It may be employed to form an effervescing draught, the proportions being as follows:—

15 grains of citric acid	will saturate $16\frac{2}{3}$ of the sesquicarbonate of soda.
℥iijss. of lemon juice	
15 grains of tartaric acid	

Bicarbonate of Soda.

If the directions given in the London Pharmacopœia for the manufacture of what is there termed *sodæ carbonas*, be strictly followed, the resulting salt is the *bicarbonate.*

Preparation.—It is prepared by passing carbonic acid gas through a solution of the carbonate of soda (subcarbonate of the shops), and crystallizing.

Properties.—This salt is distinguished from the other carbonates by not reddening turmeric paper, nor precipitating a solution of the sulphate of magnesia.

Composition.—It is said to be composed of—

2 atoms carbonic	44
1 soda	32
1 water..................	9
	85

The *physiological effects* and *uses* are similar to the last salt.

Phosphate of Soda.

History and synonymes.—As a constituent of the urine this salt has been long known, though its nature was for a long period not understood. It has been termed *alcali minerale phosphoratum*, and *sal mirabile perlatum.* In the shops it is frequently sold under the name of *tasteless salts.*

Native state.—It is found in the animal fluids, particularly the urine.

Preparation.—It is procured by adding carbonate of soda to a solution of phosphoric acid, obtained by digesting sulphuric acid on bone ashes.

Properties.—The primary form of the crystals of this salt is an oblique rhombic prism. Its taste is mildly saline. When exposed to the air it effloresces, and when heated loses its water of crystallization.

Composition.—According to Dr. T. Thomson it consists of—

1 atom phosphoric acid	36
1 atom soda	32
13 atoms water	117
	185

Characteristic tests.—That it is a soda salt is known by the different tests already mentioned for these salts. That it is a phosphate is known by the following characters: it precipitates the acetate of lead, and chloride of calcium, white; and the nitrate of silver, yellow. When made red hot it becomes the *pyrophosphate* of soda, and then precipitates nitrate of silver, white.

Physiological effects.—It acts as a mild saline purgative, chiefly valuable on account of its slight taste, and may be taken in broths almost unperceived. It is most analogous to the sulphate of soda in its operation.

Uses.—It is employed as a mild, almost tasteless, purgative for children and delicate females. On account of the phosphoric acid, it has been supposed particularly applicable to those cases in which there is a deficiency of phosphate of lime in the bones, and also in diabetes.

Dose.—From six drachms to one ounce and a half.

Sulphate of Soda.

History and synonymes.—This salt was discovered by Glauber, in 1658, and hence one of its names, *Glauber's salt*, or the *sal mirabile Glauberi.*

Native state.—It is found both in the inorganized and organized kingdoms. Thus the hydrous and anhydrous sulphate form two distinct mineral species. In the state of solution it is met with in many mineral waters; it is said also to exist in the ashes of those individuals of the *Tamarix gallica*, growing on the sea shore.

Preparation.—It is a product of some chemical processes: thus it is obtained by the sublimation of sulphate of ammonia with common salt, as also in the manufacture of muriatic acid, but the consumption of it being now enormous in the manufacture of carbonate of soda, it is obtained purposely by the addition of sulphuric acid to common salt. The theory of the process I have already explained under the head of hydrochloric acid.

Properties.—The primary form of the crystals of this salt is the oblique rhombic prism. The taste is bitter and saline. When exposed to the air it effloresces; and when heated, liquifies or dissolves in its own water of crystallization.

Composition.—In the crystallized state it consists of—

1 atom sulphuric acid	40
1 atom soda	32
10 atoms water	90
	162

Characteristics.—Its two constituents may be known by the tests already mentioned for sulphuric acid and soda.

Physiological effects.—It is a mild but efficient laxative, or purging salt, promoting secretion and exhalation from the whole mucous lining, without causing inflammation or fever.

Uses.—It may be employed as a common purge, either alone or added to other purgatives. It is applicable in fevers and inflammatory affections, where we want to evacuate the bowels without exciting the system generally.

Dose.—From six drachms to an ounce and a half. If it be dried, so as to drive off the water of crystallization, three and a half drachms of the powder will act as an efficient purgative.

Experiments and Observations on the Effects of certain Substances upon the Blood; on the Coagulation of the Blood; on the Difference between Membranous and Sanguineous Serum; on the Formation of the Buffy or Inflammatory Crust; on the Formation of Pus; on the Functions of the Lymphatic System; and on the Process of Sanguification.

By Andrew Buchanan, M.D.,
Junior Surgeon to the Glasgow Royal Infirmary.

[Continued from page 54.]

II.—*Reflections on the preceding Experiments.*

The reflections which the preceding experiments are calculated to suggest, are partly of a chemical, and partly of a physiological kind.

By far the most remarkable fact ascertained by the preceding experiments, is that when the serum of the membranes and the serum of the blood are mingled together, a coagulation takes place, during which a part of the mixed liquid passes from the liquid into the solid state, and assumes the form of a reticular membrane; or, in other words, passes from the state of liquid albumen, soluble in water, into that of fibrin, or insoluble albumen. Is there any thing in the chemical constitution of these fluids by which this coagulation can be accounted for on known principles? There is not, so far as I am aware. The similarity of properties between the serum of the blood and that obtained from the serous cavities is so great, that we should not readily expect any reaction to take place between these fluids. This similarity is much greater than the statement made in books upon chemistry would lead us to suppose. According to Berzelius, the serum of the serous cavities "may be considered as the serum of the blood, having the degree of dilution which ordinary serum would have, if mingled with seven times its volume of pure water."

This may be very true of hydrocephalic serum, from which, by a most unhappy selection, he seems to have deduced the general description he has given of the serum exhaled into the serous cavities. The assertion, however, considered as a general one, is very far from being correct. Another very erroneous assertion made by the same author, is that the liquid of the serous membranes "has always been found of a composition absolutely identical, whether it came from the ventricles of the brain, the pectoral cavity, from the abdominal cavity, or from the cavity that surrounds the testicles." On the contrary, there are at least three different kinds of membranous serum, differing from each other in qualities, and more especially in being more or less rich in albumen.

Of these three kinds of serum, the first and richest in albumen is that exhaled into the scrotal cavity, the peritoneal cavity, and the cavities of the pleura and pericardium. Next comes the fluid exhaled into the cells of the cellular membrane; and last, and least rich in albumen, is the arachnoideal fluid, or that exhaled into the ventricles of the brain and cerebro-spinal cavity. On each of these kinds of serum I shall offer a few remarks, chiefly in reference to the phenomenon here under consideration.

1st, *Serum from the great cavities of the trunk of the body.*—The serum obtained from the cavity formed by the tunics of the testicle, from the peritoneal cavity, and from the cavities of the

pleura and pericardium, seems to be always of the same kind, as might, indeed, be anticipated from the similarity of organization in the exhaling membranes. It is from the first-mentioned of these cavities that the serum is most likely to be obtained in the state in which it may be supposed to exist in the healthy body. The dropsical effusions which take place in the larger serous cavities are for the most part the effect of some severe visceral disease, by which the general health has been previously invalidated; whereas the dropsy of the testicle is a purely local affection, which may exist while the organs of digestion and sanguification are in the most healthy condition. It is, therefore, from hydrocelic serum that the general characters of this variety of serum ought to be deduced. It is a transparent liquid, of a light amber colour, and sometimes with a tinge of green; it coagulates into a solid mass on being heated; it varies in specific gravity, like the blood itself, according to the state of the general health. I tapped the same individual thrice, at the interval of some months. The first time the specific gravity of the serum was 1·0227; the second time it was only 1·0206, but he had then just finished a course of mercury, to which I conceived the impoverishment of the fluid to be owing. On tapping him, however, a third time, after he had regained his flesh and strength, the specific gravity of the serum was still less, being 1·0193. On the second of these occasions I had an opportunity of comparing the specific gravity of the membranous serum with that of the serum of the blood. Immediately after the man was tapped, I had some blood drawn from the arm, with the view of injecting the dropsical cavity either with the blood itself, or with the serum that separated from it, for the purpose of effecting a radical cure of the disease. The specific gravity of the serum of the blood was 1·0285, while that of the hydrocelic serum, as mentioned above, was 1·0206, the difference between them being only ·0079. In another case, in which I repeated the same experiment, the specific gravity of the serum of the blood was 1·0251, and that of the hydrocelic serum 1·0191; the difference, therefore, amounting only to ·006. The specific gravity of the hydrocelic serum is often greater than in the cases referred to, so that it is little inferior to the ordinary specific gravity of the serum of the blood.

It may, I think, be inferred, that in the healthy body, and probably also in the state of disease, the serum exhaled into the serous cavities we are here considering, is little inferior in specific gravity to the serum of the blood as it exists at the time when the exhalation takes place. In the state of disease, the specific gravity of membranous serum varies in all gradations downwards, till it becomes little heavier than water. I found the specific gravity of serum taken from the cavity of the pleura to be 1·0099, in a strumous subject dead of dropsy, after having undergone amputation of the thigh. In a woman tapped for ascites, the first time the specific gravity of the serum was 1·0094; and in a case in which I saw my friend Mr. George Watt tap a woman the 212th time for the same disease, the fluid drawn off was very little different from water. The specific gravity of the serum depends chiefly upon the quantity of albumen which it contains; and when the specific gravity is very low, the serum, instead of becoming solid on the application of heat, merely becomes milky.

It was with the serum obtained from the sources indicated above, that the coagulation took place most readily and completely on the addition of sanguineous serum. The phenomenon, however, as already mentioned, was not invariable. Sometimes the want of success seemed to arise from deficiency of albumen, as indicated by the low specific gravity of the liquid, and sometimes from putrefaction, the liquid having been too long kept. But as the experiment sometimes succeeded when putrefaction was far advanced, it is obvious that neither the coagulation of membranous and sanguineous serum, nor the secondary coagulation of the blood itself after the coagulum has been liquified and mixed with membranous serum, can be explained by calling it a vital operation—a form of words which some physiologists have deemed sufficient to explain the primary coagulation of the blood.

Sometimes, again, the want of success could not be referred to either of the causes just mentioned, but seemed to

depend upon a kind of elective affinity, whereby the serous liquids of some individuals harmonized together, and were easily blended into a coagulum, while those of other individuals shewed no tendency to unite. With respect to the time required to produce the coagulation, it was for the most part a slow and gradual process. I have seen the liquidity of the mixture unimpaired at the end of twenty-four hours, and in forty-eight hours the coagulation distinct. More generally, however, the coagulation was quite distinct in twenty-fours, often in a much less period; and on one occasion, when both kinds of serum were quite recent, having been taken from the body only a few hours before mixture, the coagulation took place in a few minutes, or in nearly the same time that the blood itself takes to coagulate. In no case, however, so far as was observed, did the coagulation take place at once, but, on the contrary, it often went on increasing during several days. I found that equal parts of the two liquids yielded a coagulum larger and firmer than when either of them was used in a double proportion; but I think it probable that in this respect much must depend on the relative qualities of the two liquids. Although most of the experiments above mentioned were made with venous serum, yet I may here mention, that after several failures I found arterial serum to comport itself exactly in the same manner.

Without entering into any speculation as to the cause of the phenomenon here under consideration, I may merely say, that I think it is probably one of those which the chemistry of the present day is incapable of elucidating. Nor is this the only instance of the animal fluids possessing a power of reacting upon each other of the most remarkable kind, which, nevertheless, eludes the scrutiny of the chemist. He cannot tell the difference between the laudable pus of an abscess which is innocuous in its qualities, and the pus of the small-pox pustule, which engenders a loathsome, and often a fatal disease; nor can he distinguish it either from the pus of a chancre, very different, but scarcely less formidable, in its effects.

2d, *Serum from the cellular membrane.*—The second kind of serum mentioned above is that obtained from the cellular membrane. It is scarcely possible to obtain this kind of serum in the state in which it may be presumed to exist in the healthy body. In cases of œdema, or mere local dropsy of the cellular membrane, we seldom draw it off; and when we do, it is necessarily mixed with much blood. Again, in cases of anasarca, or of general dropsy, from which it is easily procured, the bodily health is so much undermined, that the whole humours of the body are necessarily in a state of great attenuation. The serum obtained from the cellular membrane in these last-mentioned cases is a colourless transparent liquid, like water. It has little or none of the saponaceous feel so remarkable in the serum last described, and in that of the blood. It never becomes solid on being heated, but merely assumes a milky colour, or at most shews a few flocks and filaments. In only one case I tried its specific gravity, and found it to be 1·0081. I tried this serum with the serum from the blood of two different individuals, and also with some peritoneal serum; but in none of these instances did coagulation take place. The trials I made with another specimen were not attended with any better success; but it obviously does not follow from these experiments that the liquid of the cellular membrane, as it exists in the healthy body, is not capable of coagulation when mixed with the serum of the blood.

3d, *Arachnoideal serum.*—The serum obtained from the cerebro-spinal cavity, and from the ventricles of the brain, seems to be of the same kind. On the 20th ult. I obtained an ounce of serum from the ventricles of the brain, and about as much from the cerebro-spinal cavity. That from the ventricles of the brain was as limpid as water; it had no saponaceous feel, and on being heated it became opaline, but without in the least degree losing its liquidity; its specific gravity was 1·0098. The liquid from the cerebro-spinal cavity seemed to be exactly similar in qualities; but as it cannot be collected in any considerable quantity unmixed with blood, it was of a red colour; and to the same circumstance must have been owing its higher specific gravity, which amounted to 1·0156. In another experiment the specific gravity was 1·0123, but it also contained blood. The only difference of qualities that I could perceive, was

that the liquid of the cerebro-spinal cavity seemed to dissolve the blood, while that of the ventricles continued quite limpid, the blood settling at the bottom; but this was in all probability owing to the much greater quantity of blood in the former case. In several experiments made by mingling these liquids with the serum of the blood, an imperfect coagulation took place, while in a still greater number there was no coagulation.

4th, *Serum of blisters.*—It appears to me probable, that besides the varieties of serum mentioned above, there may be other varieties, which receive peculiar modifications in the vessels of particular tissues. I have often examined the serum obtained from the blisters which form on the surface of the skin, from the action of irritants like cantharides, or from burns or erysipelas. This kind of serum is transparent, and of a light yellow colour, like that obtained from the great serous cavities. It generally coagulates into a solid mass on being heated. The specific gravity of one specimen I found to be 1·0213, and of another 1·0219. It appeared to me from these properties to be probable that this serum would be of the same nature as that of the serous membranes, and I therefore anticipated that coagulation would take place on mixing it with the serum of the blood. In this expectation, however, I was deceived, as I ascertained by numerous experiments. On reflecting again that this serum was probably not produced by exhalation, but by effusion from ruptured vessels, I came to think that it might be more akin in its nature to sanguineous serum. I accordingly tried the effect of mixing it with membranous serum; and although the experiment was never made under very favourable circumstances, it several times succeeded partially. The success was most complete in an experiment made with the serum of an erysipelatous bulla, of specific gravity 1·0195.

There appears to me to be still another kind of serum, formed upon the surface of the skin, and which, probably, in the healthy state, is exhaled into the interstices of the rete mucosum, under the cuticle. It is impossible to obtain this liquid distinct from the former, and it is, therefore, only by a process of reasoning that we come to recognize its existence. It is well known that upon the surface of the skin, when denuded of the cuticle, there forms a fibrinous layer, or, as it is commonly called, a coating of coagulable lymph; this colourless coagulum, or fibrinous substance (for according to the views stated above, these terms should be considered as synonymous), I believe to result from the reaction of the two kinds of serum just mentioned.

An interesting observation made by Mr. Lumsden, to whose intelligent assistance I have been much indebted in the prosecution of these researches, tends to confirm this view of the origin of this substance. After evacuating the serum from a blister on the skin, he removed the cuticle; he removed also the fibrinous layer with which the surface of the cutis was covered, and pressing this substance between his fingers, as we do a wet sponge, he received the expressed liquid in the vessel containing the blister serum. The result was the formation of a colourless coagulum, which, had it been found on the surface of the skin, must have constituted an additional layer of coagulated lymph. In this way the whole liquid in blisters which are not opened, and do not suppurate, is often converted into a solid fibrinous coagulum.

It appears to me probable that coagulable lymph, or the plastic humor, as it has been named by M. de Blainville, has a similar origin, in whatever part of the body it be formed. The colourless coagula, or polypi, as they have been termed, often observed in the cavities of the heart, and some other analogous phenomena, to be mentioned hereafter, appear to me to indicate that a serous fluid is exhaled from the lining membrane of the sanguiferous system, which undergoes coagulation on being mixed with the serum of the blood.

[To be continued.]

PHOSPHATES IN URINE—CAUSE OF THEIR DEPOSITION.

To the Editor of the Medical Gazette.

Sir,

Having observed in the Guy's Hospital Reports of this month some remarks on the cause of the deposition of the phosphates in urine by mere boiling, and having also noticed that the explanation which I have offered of this phenomenon, in my recent papers published in your journal, is objected to, I have been induced to institute the following experiments.

Some urine, depositing the mixed phosphates by standing, was found decidedly acid in its reaction on litmus paper at the moment of its emission; it was also clear, and of specific gravity 1007, very low. This, however, depended upon the diluted condition of the secretion, the urine having been voided shortly after breakfast.

1. Upon boiling a portion of this urine it became turbid, not unlike albuminous urine. The turbidity, however, was entirely removed by nitric acid. The urine remained acid after boiling.

2. A portion of the urine was allowed to stand for five or six hours undisturbed; small brilliant crystals of the triple phosphate manifested themselves on the surface of the fluid, and on the sides of the glass: the urine was still faintly acid. It was then left untouched in a cool place for two days: the deposition of phosphatic salts increased, and the urine exerted no appreciable action on litmus or turmeric paper.

3. A portion of this urine was then filtered and boiled. Scarcely any change was produced by heat.

These experiments lead me to believe, that during the exposure of the urine to the atmosphere, something was given off which had previously held the phosphates in solution. Now phosphoric acid could not escape, it being a fixed acid. The only agent which is volatile, and a solvent of the earthy phosphates, found in urine, is carbonic acid. When I make use of the term volatile, I mean capable of passing into the atmosphere at the ordinary temperature. It did not depend upon the formation of ammonia, because the fluid was not alkaline, nor capable of evolving ammonia by mere heat. This urine, however, as does almost all phosphatic urine, became alkaline after having been kept for several days. The fact, also, of this urine becoming exceedingly turbid when first passed, by boiling, and after standing some time being scarcely or not at all affected by heat, confirms the opinion, that the deposition was the result of the evolution of carbonic acid.

A. Some urine of the same description, and recently voided, was placed under a receiver, full of hydrogen, with a shallow glass capsule, containing lime-water; the gas was confined by means of a saturated solution of common salt, boiled so as to drive off any gaseous matters contained in it: a concentrated solution of common salt will absorb little or no carbonic acid.

B. The same quantity of urine was placed under the same circumstances, common atmospheric air being used instead of hydrogen gas. After two hours, or thereabouts, the urine placed in the hydrogen was found turbid, and the lime-water contained on its surface a film of carbonate of lime; that which had been placed in mere atmospheric air was unchanged.

These experiments clearly prove, that a solvent had been removed in the one case, and not in the other, and that this solvent was carbonic acid,—the agency of heat having been entirely dispensed with.

It has been objected to the opinion I entertain, that carbonic acid is the solvent in such cases, of the phosphatic salts, that urine yielding this deposit by boiling is more acid after than before ebullition, and certainly the fluid, when hot, seems to redden litmus paper more readily than when cold. I believe, however, that this depends upon the fact, that a hot fluid permeates more readily the tissues of the test paper, and, consequently, comes more in contact with the colouring matter with which the latter is imbued; for, if the boiled urine be allowed to become cold, it does not then redden litmus paper more distinctly than it did before boiling: the following experiments go to show, that the urine does not in these cases contain more, but in many cases less, free acid after than before boiling.

1. A given measure of urine, yielding the phosphates by boiling, was heated with tincture of litmus, so as to become distinctly red; to this a weak solution of caustic ammonia was added guttatim, by means of a dropping tube, containing a fine capillary bore at the end of it: the number of drops necessary to render the fluid blue were five.

2. Another equal measure of the same urine was boiled, and the loss sustained by evaporation supplied by distilled water: when cold, litmus tincture was added to redden it. Ammonia was added guttatim: two drops were found sufficient not only to destroy the red colour, but even to give the fluid a slight green tinge.

3. Healthy urine was treated in the same manner; thirteen drops of a solution of ammonia were found necessary to render the reddened fluid blue, in the case where the urine had not been previously boiled, and only eleven in the case where that operation had been performed: these experiments were repeated with different specimens of urine: in some cases, the quantity of ammonia necessary to restore the colour to reddened litmus was nearly the same both before and after boiling; in the majority of cases, however, a smaller quantity was necessary after boiling, and in no one case was more required after than before boiling.

The explanation which has been offered, both of the cause of the deposition of the phosphates by mere heat, as well as of what is called the superior acidity of such urine after boiling, in the Hospital Reports before alluded to, the Editor considers as quite satisfactory; I cannot, however, agree with him in this particular. He there states, upon the authority of Mr. Rees, that the muriate of ammonia is the solvent agent, and that boiling causes the phosphates to be thrown down from their solution in the above salt, and that the urine is more acid, in such cases, after boiling, from the decomposition which the muriate of ammonia suffers—a portion of the volatile base of that salt being driven off by heat.

With respect to the power which muriate of ammonia possesses over recently precipitated phosphate of lime, that is, and has been long, well known and universally acknowledged; and it is also known that, under *certain conditions*, heat causes a precipitation of the phosphatic salt from such a solution. I find, however, from my own experiments, that if the muriate of ammonia be in excess, no precipitate of the phosphate is affected by boiling, also if any notable proportion of free muriatic acid be present. But muriate of ammonia is not singular in this property of dissolving recently precipitated phosphatic salts. Muriate of potass, or soda, possess the same property, as do also the nitrates and acetates of the same bases, the latter in a less degree however. Now in the latter cases it is manifest that mere heat cannot decompose the solutions of the salts, and muriate of ammonia, as I shall presently shew, is not decomposed by boiling its solution in water; the phosphatic salts are not, therefore, precipitated, because of the decomposition of their solvents.

It is well known to chemical analysts, that certain acids and bases may exist together in a fluid, under certain circumstances, without forming insoluble salts until heat is applied; thus, a weak solution of phosphate of ammonia may be mixed with a diluted solution of a magnesian salt, without any precipitate taking place, at least for some time; the application of heat, however, immediately causes a deposition of the triple phosphate; the same thing obtains when phosphate of soda is employed instead of phosphate of ammonia. Again, a weak solution of an alkaline sulphate causes no precipitation in a diluted solution of a calcareous salt until heat be applied, when, immediately, a precipitate of sulphate of lime ensues. Now, in all these cases, the deposit takes place by the mere agency of heat, without the loss of any solvent, and in these instances, as well as in the case of the phosphates being thrown down by mere heat from their solution in certain alkaline salts, the phenomena are due, not to the decomposition or removal of any solvent, but to the increased temperature to which the fluids are exposed, causing the particles, constituting the insoluble salts, to come more closely together, by virtue of an increased chemical attraction. But to return to the question,—do the earthy phosphates exist, in certain specimens of urine, in such a state of solution in muriate of ammonia as to be precipitated by the application of heat? That such a state of things may occa-

sionally prevail, I would not deny, but I confess that I do not believe that this explanation is correct in any of those cases in which urine suffers the phosphates to deposit by repose, and also yields a further deposition upon the application of heat; for, in the experiment related just now, in which phosphatic urine, after remaining two days at rest, yielded little or no deposit upon boiling, although, when first voided, a copious precipitate was caused by heat, mere atmospheric exposure could not have removed any muriate of ammonia, and, therefore, heat ought to have caused the deposition to take place, after the urine had remained for two days at rest, as fully as it did at the moment of its emission, supposing always that no free alkali had been generated; and that this urine was found acid after exposure for some hours, and certainly not alkaline after remaining exposed for two days, renders it improbable that any free alkali or alkaline carbonate had been formed. In the experiment, too, in which the urine was placed under hydrogen, it is quite impossible to believe that the muriate of ammonia was the solvent; indeed, we have the clearest evidence that it was carbonic acid. I shall say but a few words, which, I think, will be sufficient to show, that the belief that such urine, or indeed any urine, actually contains more free acid after than before boiling, is unfounded, and at variance with the results obtained by direct experiment; indeed, the experiments with tincture of litmus sufficiently point out the fallacy of this opinion, and therefore the fact itself being disproved, the hypothetical deductions must fall to the ground.

It is, however, advanced in explanation of this assumed condition of the urine— viz. its increased acidity after boiling—that a portion of ammonia is driven off: it remains to show how far this statement is borne out by experiment.

1. A saturated solution of muriate of ammonia was boiled in a flask with a long narrow neck, in which a portion of turmeric paper was suspended; although the ebullition was continued for some time, the turmeric paper was not in the slightest degree reddened.

2. A diluted solution of muriate of ammonia was treated in a similar way, with the same results.

3. A portion of muriate of ammonia was placed, *per se*, in a flask, and heat applied, until a considerable portion was sublimed; no ammoniacal vapour was evolved, the turmeric paper not being acted upon.

4. A solution of muriate of ammonia, holding the earthy phosphate in solution, was boiled in the same way, and, although the latter salt was precipitated, no ammonia was evolved.

It is, therefore, clear, that muriate of ammonia does not part with any of its base, either at a boiling temperature, or even at a temperature sufficiently high to cause it to sublime; neither does the presence of the earthy phosphate cause an evolution of the ammoniacal base.

I find, also, that the bi-phosphate of ammonia, (it is this combination of the acid and base which exists in urine,) does not part with any of its ammonia at a boiling temperature, the base being evolved only at a temperature necessary for the fusion of the salt. To sum up,—from these experiments, as well as from those formerly published, I am disposed to conclude—

1st, That in all cases where the phosphates are deposited, either by simple repose or by boiling, from urine remaining *acid*, that such a deposition is caused by the removal of carbonic acid, which acted as the solvent.

2dly, That under certain conditions of the urine, it is not improbable, but far from being clearly proved, that the phosphates may be held in solution by muriate of ammonia, or even by muriate of soda, and that heat causes them to be precipitated from such solutions.

3dly, That urine does not, under any circumstances, contain more free acid after than before boiling.

By inserting these remarks, you will oblige,

Your obedient servant,
R. H. Brett, M.R.C.S.

ON THE AGENCY OF IODINE IN ULCERATION.

To the Editor of the Medical Gazette.

Sir,

I will thank you to insert, in your next number, the following remarks on the agency of iodine in ulceration, elicited by a critique in the Messrs. Johnson's Review for this month, page 413.

This valuable remedy, which has of late years been added to our list of remedial agents, exerts a peculiar influence in checking that form of inflammation that leads to ulceration. Its efficacy in controling this action has been so extensively demonstrated in the wards of our hospital, and its virtues in enabling tissue to resist ulcerative action have been so fully tried and acknowledged, that I had almost regarded this action of iodine as settled beyond dispute. Still less should I have thought of making it the subject of a distinct notice, as I considered its action too well known and understood to require the attention of the profession to be drawn to so notorious a fact in therapeutics.

A long course of experience having impressed me strongly in its favour, I should have remained in a state of ignorance, as it seems, of the general opinion entertained of the action of iodine, had not one of our intelligent pupils directed my attention to a startling paragraph in Dr. Johnson's Medico-Chirurgical Review, for April last. It occurs in a critical review of my paper on the subject of ulceration of cartilage, in the last volume of the Transactions of the Royal Medico-Chirurgical Society. My observations, that called forth this critique, are these :—

" It is difficult to explain or to reconcile the action of some remedies, with the supposition of absorption being concerned in ulceration. One of the most powerful remedies that we possess, and that exerts a remarkable control over the ulcerative process, is iodine. The most active phagedænic ulcers, that threaten the destruction of parts, are often found to yield, in a surprising manner, to the influence of this medicine, and to put on a healthy granulating appearance: and yet iodine is thought to act powerfully in increasing the action of the absorbents; tumors of considerable size often yielding to its action, and being absorbed. How is it that, in the healing of an ulcer, it checks and puts a stop to the absorbing process, and, in the case of a tumor, quickens the action of the absorbents and gets rid of the mass? Here are two actions of a remedy opposed to each other, and inexplicable, so long as ulceration is regarded in the light of absorption. In the same person, and often on the same limb, we see the beneficial effects of iodine in the arrest of a spreading cachectic ulcer, and the absorption of a venereal node or periosteal effusion; two actions that present a paradox to those who view ulceration as effected through the agency of the absorbents. But the action of this and other remedies that arrest the progress of ulceration is effected through another medium than the absorbents; it would seem to depend on some additional nervous or vital power imparted to the ulcerating surface, by which its vital energies are reinforced, and which enable it to resist those repulsive forces that tend to disorganize it."

On this the reviewer makes the following strictures:—

" If Mr. Key could prove that iodine was a great promoter of absorption, and at the same time one of the most efficient agents in checking rapid ulcerative action, we should admit that there was plausibility in this argument. But we differ, *toto cælo*, from Mr. Key, in his very premises. We deny that iodine is an efficient remedy in cases of phagedænic ulceration. Nay, we will go farther, and affirm, as a general fact, that iodine is one of the very worst remedies that could be administered in phagedæna. Our readers must observe that phagedænic ulceration may occur in circumstances diametrically opposite, —in a state of system requiring depletion, and in a state of depression and extreme irritability. The former, so far as we have seen, is the exception, the latter the rule. It is possible that in the former, iodine may now and then be beneficial. We are certain that in the latter, opium, the volatile alkali, stimuli, are the remedies to which the surgeon must trust. These are the remedies that build up, rather than pull down; and as reason suggests their use, experience justifies it. On this point

we can speak with the positiveness of careful and extensive observation; and here, on the premises of the argument, we are opposed to our author."

The uncourteousness of the reviewer, in denying a fact which I have advanced in testimony of the powers of iodine, is the first complaint that I have to make against him. Had he confined himself to the denial of any matters of opinion, or of any inference from the facts that I might have stated, I should have left him peaceably in the enjoyment of his own peculiar views. But his denial extends to the facts that I have advanced: he denies what I state as a matter of fact, and not of opinion—that iodine is an efficient remedy in checking ulceration. In his ardent desire to write me down, he is not content with restricting his opposition to my views of ulceration, but places me (I trust inadvertently) in the position of a person desirous of maintaining his peculiar views by falsifying facts, and bending them to his purpose.

Had I been aware that there existed any person, calling himself either physician or surgeon, ignorant of this peculiar property of iodine, I should, at the risk of being tedious, have mentioned some facts and cases, out of the many that I have witnessed, in the paper that I read before the Royal Medico-Chirurgical Society. But conceiving that a detail of such well-known properties was only adding to the length of the paper, and nothing to its illustrations, I was content with the simple statement of the power of this remedy; or, if I could have supposed that what was well known to every six months' pupil of our hospital, could possibly be unknown to a learned body like the Royal Medical Society, I should have detailed at length the facts on which my statement was founded. A reviewer, however, appears to be altogether of a different genus—a *tertium quid;* and never thinking of addressing my observations to him, I have failed to make that allowance for his backwardness in the science of the day, which appears to be necessary. It is my purpose now, in part, to supply that deficiency, and to free myself from the reviewer's implied charge of advancing what is unfounded in fact.

"If Mr. Key could prove that iodine was a great promoter of absorption, and at the same time one of the most efficient agents in checking rapid ulceration, we should admit that there was some plausibility in his arguments." This is his statement of the problem to be solved—the Q. E. D. of the reviewer. I believe that a simple affirmation of such cases having been admitted under my care in Guy's Hospital, and cured by the action of iodine—of such cases having been witnessed by the gentlemen attending the surgical classes, as well as by many of my colleagues—would be sufficient to establish the fact in the estimation of my professional brethren. The reviewer will not, perhaps, be hardy enough to make as light of their testimony as of my assertion. For a very long period I have been in the practice of using iodine in phagedænic ulcers, both in hospital and in private practice, as a remedy on which great reliance can be placed. Indeed, for several months together I employed no other remedy in the treatment of these ulcers, in order to ascertain in what form of sores its action was beneficial; and there was scarcely an instance of cachectic spreading ulcer that was able to resist the healing power of this medicine. It is not only a good remedy, but, I think I may say, next to opium, the most useful and the most certain in its effects. It is in that kind of ulcer termed, from its destructive nature, phagedænic*, that its action is best displayed. By phagedænic, I understand that kind of sore in which inflammation is speedily followed by ulceration; in which the vital powers of a part are so enfeebled by a cachectic condition of the frame, that as soon as inflammation attacks the skin and cellular membrane, they break down and become disorganized. This action differs from sloughing, in the texture not dying till it passes into a fluid state: in sloughing, the integrity of the skin is preserved, while its vitality is passing away; it therefore sloughs as a mass: in ulceration, on the contrary, the tex-

* To prevent any disputatious objections to my interpretation of the term phagedænic, as applied to an ulcer, I beg to refer the reader to my original use of it in the paper in the Medico-Chirurgical Transactions. It is quoted at the commencement of the present remarks. It will be evident that I there employ the term to exemplify the irritable spreading ulcer, in which iodine enables the natural powers to resist the ulcerative action, and to reconstruct the texture that is lost.

ture is softened down by a living action, and a fluid depôt is the result of the change. It is to this form of ulceration that the action of iodine is opposed; it is this kind of disease which iodine arrests. Ulceration and sloughing are not unfrequently seen together in the same destructive sore. In the soft palate of the female, in which a few hours would seem to make a difference in the destructive progress of a phagedænic ulcer, I have seen iodine arrest the ulcerative action, and in forty-eight hours cover the sore with healthy granulations. I make these assertions, knowing that these cases have been witnessed by many who can speak to their truth, and that the cases are not few in which these powers of iodine have been publicly displayed. In rapidly spreading ulcers of the face and leg, even when combined with a disposition to slough, occurring in persons whose constitutions have been enfeebled by dissipation, the same sanative power has been repeatedly seen in the wards.

"We differ *toto cœlo* from Mr. Key in his very premises. We deny that iodine is an efficient remedy in cases of phagedænic ulceration; nay, we will go farther, and affirm, as a general fact, that iodine is one of the very worst remedies that could be administered in phagedæna."

The gentleman who penned this paragraph is evidently a person of very small experience; one who has gathered his notions of the action of iodine from the bugbear tales of a former age, in which we heard nothing of its effects but absorption of the testicles of the male, and the mammæ of the female. With emaciation and other horrors, I had imagined that all these idle stories of iodine were confined to old women of other days, and that boys now threw them aside with their nursery books. Perhaps the reviewer is too young and inexperienced to have done with the latter, and therefore entertains an infantile horror of the effects of iodine. If this be the case, I would advise him speedily to extend his experience, and, in the interim, to pause before he ventures to doubt and denounce the assertion of more experienced persons, in respect to any remedy the benefits and action of which he may have yet to learn. Where this young gentleman has passed his time since the period of his pupillage is not easy to divine; certainly not in a metropolitan hospital, for there can scarcely be one that does not, like Guy's, afford abundant evidence to give a direct negative to his assertion; he is, indeed, far behind the practical knowledge of his own times. It may be that he passes his time in the recess of his closet, learning the art, or the mystery, of reviewing. Practical surgery is one thing, reviewing another. Let me assure him that the latter is a bad school for learning his profession practically, or even for acquiring liberality of feeling. I speak not from personal experience in reviewing, as I never wrote a review; but I judge, as in the present instance, from the fruits of those who do.

"Phagedænic ulceration may occur in circumstances diametrically opposite, in a state of system requiring depletion, and in a state of depression and extreme irritability. It is possible that in the former iodine may now and then be beneficial. We are certain that in the latter, opium, the volatile alkali, stimuli, are the remedies to which the surgeon must trust." Here, again, the reviewer is quite wrong in his description of cases to which iodine is applicable. "It is possible," he says, "that in the former, that is, in phagedænic ulceration occurring in persons requiring depletion, iodine may now and then be beneficial." I believe that I speak the sentiments of all who are conversant with the use of this medicine, in saying that these are precisely the cases in which it is found to be prejudicial. Iodine, when used properly, is a powerful stimulant and tonic; it excites the pulse, and increases its volume; it stimulates the stomach, increases the appetite, and fattens the patient; it gives tone to the extreme vessels and nerves of an ulcer, and prevents the inflamed texture being destroyed by ulceration. We should expect, therefore, that a medicine possessing these powers would not exactly be the remedy to be depended upon in persons requiring depletion; and we find that experience, as well as principle, forbids its use in such cases. I have tried it in all varieties of constitutions, and it is in those persons especially who have inflammation of the tonic character, that it is to be avoided. It is in sores attended with subacute inflammation, requiring depletion, that iodine pro-

duces its worst effects. Like all valuble remedies, it may be pushed to extreme, and may do harm. In persons labouring under slight inflammation requiring depletion, if persisted in, it quickens the pulse, flushes the countenance, produces dryness and a sense of heat about the fauces, uneasiness in the stomach, and a parched state of lips. Erythema of the gastric mucous lining probably follows its use in these cases; and gradually emaciation, with pyrexia, is the consequence. The local affection, as might be expected, is not improved by it, when such proves to be its action on the constitution. Again, it is in the very cases in which the reviewer denounces it that I find it to be a most useful remedy. In cases of ulceration, combined with depression and irritability, I use it most extensively, and with a result that entitles it to rank among our best remedies, for its sustaining powers. It is in constitutions worn down by depressing causes, when the skin is pallid, the tongue flabby, the pulse feeble, the nervous system tottering and irritable, that the building-up powers of iodine are seen to most advantage. I find it more efficacious in healing such ulcers in such constitutions than even the volatile alkali, or bark, or opium.

Mr. Edward Cock, who prescribes for the surgical out-patients, also assures me, that he finds iodine an almost indispensable remedy in phagedænic ulceration, and one on which he places the greatest reliance.

The conclusion that I naturally come to, is, that the reviewer, notwithstanding "he speaks with the positiveness of careful and extensive observation," and with the usual volubility of a professed writer, and with equal positiveness denies my statements of the efficacy of iodine, is, in truth, wholly unacquainted with the action of this remedy in ulceration.

A FEW words more, before I have done with Messrs. Johnson, and their review. It may be thought by some, that I had better omit what I am about to say; but not being desirous of recurring to so ungracious a subject, I will take the opportunity of making a remark or two on the other parts of their critique on my two last papers in the Med. Chir. Transactions.

Throughout the whole of the two notices which they have bestowed on my papers, there is manifested such a desire to run down my views, and the arguments by which I endeavour to support them, that on several occasions their hostility has been pointed out to me by persons who have been struck by their unfairness. Indeed, one friend prepared me beforehand for the attack, and assured me that they would be severely handled in the forthcoming number of the Med. Chir. Review, because—they were opposed to some of the opinions of Sir Benjamin Brodie.

Severly handled, indeed, they have been—sifted, I should have said: on looking into the review, I find the expression is "closely sifted." "Mr. Key's arguments seem, when closely sifted, to be these." Closely sifted, with a vengeance—so closely sifted, that the reviewer has ingeniously managed to let fall all the grain, and retaining the chaff, exclaims, here is the sum and substance of Mr. Key's arguments. Throughout the whole of the two reviews in question, there is not a single line of approbation—not one word, or one idea, in which the reviewer is pleased to concur. The whole he denounces, from beginning to end. Neither the facts nor the arguments please him; all must be written down—all is written down—and all because—my views do not agree with those of Sir B. Brodie.

An indifferent person might suppose that two (not short) papers made up of pathological facts and arguments derived from a variety of sources, could not fail to contain something, however unimportant, which might fall in with the reviewer's notions of fitness; and that, if I had not been fortunate enough to advance many facts or arguments possessing force or soundness, I might, by accident or by mistake, have stumbled upon something like sense and reason. But no—the reviewer cannot find a single ray of light throughout the two papers. All is denounced as darkness and error; my facts are denied, or doubted; my arguments are perverted and obscured; the reviewer cannot find a single word or idea to applaud, because—it would be heresy to see any merit in arguments ever so little opposed to the opinions of Sir Benjamin Brodie.

"The free discussion" in which the

reviewer indulges, and for which he says no apology is due to me, consists in, first, "closely sifting" my arguments in his own peculiar sieve, and then presenting them to his readers in the dress he chooses to give them. And I will do him the justice to to say, that he has managed most ingeniously to preserve the appearance of impartiality, and to rob of its point and force, all that I have advanced. The adroitness of the manœuvre might almost compensate for the want of ingenuousness, if good faith and folly were acknowledged as twin virtues. But the world is not so degraded—we are not yet arrived at that point in morals—as to identify them; and the distinction, unfortunately for the reviewer, is still recognized. To have treated me with fairness would not have answered his purpose; he must have admitted some of my statements to have some shew of probability; but his measure of approbation never rises so high. Even a cold acquiescence is withheld: he goes no nearer to the point of commendation than to say, that if so-and-so had been proved, "then, but not before, we will admit that there is *some** force in his argument." To have admitted more than this (he could not well admit less) would, in the liberal reviewer's estimation, have detracted from the merits of Sir Benjamin Brodie.

Having, as he says, first "closely sifted" the arguments, and having pretty well got rid of the grain which might, by its weight, have embarrassed him, at the conclusion of the review he submits it, *i. e.* the chaff, to a second mechanical process—that of the screw. After giving what he is pleased to term a review of my arguments, he condenses it, *i. e.* the chaff, by a process of compression. "Let us turn," he says, "to the application of the preceding arguments. It seems, when compressed, to amount to this." Now it requires not a conjuror to say what closely-sifted chaff, well compressed, probably in a screw-press, will amount to in weight, nor what compass it will occupy after undergoing this process. The instruments are ingeniously contrived for reviewing, and are well adapted to reduce the bulk and weight of facts and arguments; and the Messrs. Johnson will do well to secure a patent for their sieve and press, because, if they will answer no other purpose, they will be useful in their hands for sifting and condensing the writings of all who dissent from the doctrines of Sir Benjamin Brodie.

The question that I put to my friend will naturally be asked by any one who reads this—Why do the Messrs. Johnson covertly oppose and try to stifle the voice of those who trespass, unwittingly it may be, on the ground which Sir Benjamin Brodie has passed over? When my first paper appeared in the Transactions, I was warned of what I had to expect from this review, and I inquired why they should direct their artillery against me, who had never written one word against them, nor used an unkind expression, nor, to the best of my knowledge, ever given them cause of offence. "Oh," was the reply of my friend, "they will not attack you openly by abusing you—they will only write you down, and quietly strangle you. You have dared to write on the subject of joints, and the reviewer, to render himself acceptable, as he imagines, to Sir Benjamin Brodie, will not allow a word to stand that has the semblance of opposition to his views." Still I remained unenlightened, and again asked him the reason of the Messrs. Johnson devoting themselves to the defence of this distinguished surgeon. "Then you are unacquainted with the tactics of the Johnsons?" I confessed my ignorance, and said, that living so far to the eastward, I was but little acquainted with the politics of the profession and its journals. "I will give you a little insight into their tactics: they are perfectly well known to us of the West; we care nothing about them, and still less think of replying to their strictures, as we think them ignoble game." I did not understand what he meant by this last expression, which I thought sounded odd; and he gave me no time to inquire, but began to initiate me in the mystery of the review, which I was not a little anxious, I confess, to fathom.

"You must know, then, that one of the Messrs. Johnson is a candidate in future for the honours of the profession, and is an *attaché* in some shape to a school lately established in the far West. To both these objects he makes his review subservient, and for both he

* This word is printed in italics in the review.

wishes to have the assistance and support of Sir Benjamin Brodie. You will observe that in all his reviews he is careful, most careful, to drop nothing from his pen at all likely to annoy that eminent surgeon, but seizes every opportunity of applauding, *un peu fort*, it may be, whatever comes from his pen or from his lips, and of victimizing all who are guilty of *lèse majesté*. You are guilty, and will make a good subject to offer up at his shrine; depend upon it you will be broken upon the wheel,—quietly enough, perhaps,—for they will take care to stifle your cries; but your fate is decided. Your *disjecta membra* will then be offered up as a sacrifice; or perhaps you will be smothered *en masse* (doubtless prophetic of the screw-press), and afterwards offered as a holocaust on the reviewer's altar of adulation." Here the dialogue ceased, for I was struck dumb with amazement at the atrocity of the sacrifice, and perhaps not a little with horror at my impending fate.

Here, then, lies the cause of the unhappy fate (as far as the review can seal it) of my papers on ulceration,—herein consists the gravamen of my offence. I have dared to observe for myself, regardless of the views of others, and to put together the results of my observations, thinking that they might do some service in advancing surgery, to the interests of which I confess myself to be devotedly attached. I have dared for some years past to watch the progress of disease in joints, especially the process of ulceration; and having formed views of it in some respects peculiar, have had the boldness to publish them. I differ in no points of importance from Sir Benjamin Brodie, but only have endeavoured to add something to his contributions towards the elucidation of the diseases of joints. The reviewer forbids it,—truth must be stifled,—no one shall approach the sacred ground.

If it should be thought that I have used the name of this distinguished surgeon lightly, I shall be forward to make every amends in my power. But I think that I know him better than the Messrs. Johnson do, inasmuch as my knowledge and respect for him are disinterested, and what I do know of him, leads me to believe, that he will only smile at my exposure of the littleness of the reviewer. Sir Benjamin's reputation and labours rest on a more secure foundation than the ephemeral support of the Messrs. Johnson's Review. By a long course of labour, he has earned reputation and rank, to which he is justly entitled, and far beyond any thing that can ever fall to my humble lot. It is altogether foreign to my nature to pull down one stone from the fabric of the reputation which this distinguished member of our profession holds among us; and the reviewer will, perhaps, hardly understand me when I tell him, that no adulation from him, and no sacrifice of the characters and labours of others, however humble, or however exalted they may be, will really add one leaf to the deserved laurels of Sir Benjamin Brodie.

The application of the term "scientific resurrection-men" is in keeping with the general tenor of the review. The good taste of the writer may be questioned by those who see nothing either barbarous or degrading in recurring to the practice of former surgeons, and who may think that the expression might have been dispensed with. I have, and with pleasure confess it, exhumed the operation of Petit, of leaving, in some cases, the hernial sac unopened, and have, therefore, laid myself open to the good feeling and mercy of this charitable reviewer. I cannot, however, omit adding, that I have given to every one, who has had any share in promoting the operation, his full meed of praise and credit. Yet I claim no merit to myself on this ground; I have only acted in accordance with the invariable rule that has guided my respected preceptor Sir Astley Cooper,—of rendering credit to those to whom credit is due. Moreover, I am content to bear any odium that the Messrs. Johnson may be pleased to cast upon me, provided that the fair-judging part of the profession be not blinded by the dust which those gentlemen design to throw in their eyes.

These observations I have thrown together for the purpose not of attack but of defence. I am not inclined to disputation, unless when the latter object demands it; and then I do not hesitate to gird my loins for the combat. The Messrs. Johnson have not openly avowed their hostility, but have quietly tried to demolish me with a masked battery, under cover of a fair show of reasoning and criticism. I am

not to be easily crushed in this way, at least, not without some shew of defending myself. Open hostility, or an avowed attack, would have been passed by unheeded; of the motives, as well as of the efficacy, of such a mode of warfare, those who read the attack can always judge; it is only the covert enemy, who escapes detection and exposure, until he be pointed out by the finger of the injured, that I think it worth while to resist.

The sneer which the Messrs. Johnson bestow on my advocating the "salutary efforts of nature," only convinces me, that I have been educated in a different school from the reviewer, where I have been formerly taught, and now teach, this same beautiful, as it appears to me, doctrine of the beneficial provisions of nature shewn in the protection afforded us against the destructive operations of disease. I am content to remain in this state of ignorance and prejudice, if it please the enlightened reviewer so to consider it. Moreover, I will throw out for the wonderment of this gentleman, another equally strange axiom, namely, that the attacks of reviewers are much less hurtful than many squeamish persons are inclined to believe; and for this reason—that it is not in the power of a reviewer to do more than for a time to throw a veil over the truth, or to stifle its voice. The moral government of the world is otherwise arranged than to allow man to injure the character—mind, Mr. Reviewer, I say character—of his fellow man. Physical force is, doubtless, allowed to prevail, as it is in the brute world; but in that which distinguishes man from the beasts that perish—the mind—he is safe; no human being can injure or debase the mind of another; this lies only in his own power; by himself only can man be thus injured. This doctrine, I dare say, like that of the salutary efforts of nature, will be received by the reviewer with derision. Nevertheless, I am a believer in both.

"Truth being my object, the free discussion," in which I have indulged, requires me to make no apology to the Messrs. Johnson; I shall, therefore, conclude, by subscribing myself, sir,

Your obedient servant,

C. Aston Key.

St. Helen's Place,
April 12, 1836.

LITHOTRIPSY.

BARON HEURTELOUP AND SIR CHARLES BELL.

To the Editor of the Medical Gazette.

Sir,

I have been much gratified at the friendly and liberal manner in which Sir Benjamin Brodie has explained (I am willing to believe) an *error* into which Sir Charles Bell had fallen, in the description of an instrument supposed to have been used by the Baron Heurteloup, at an operation performed on Colonel Rowkin, nearly four years ago

This explanation, so far as it goes, probably sufficiently sets at rest that point; but I feel much regret that Sir Benjamin did not enter more fully into the circumstances connected with the operation, to shew that statements with regard to the entire case, and its consequences, have been uncharitably and recklessly promulgated in Sir Charles's clinical lecture, delivered at the Middlesex Hospital School, on the 14th March last.

This *extraordinary* lecture abounds with so many misstatements, or mistakes, in addition to the point before mentioned, that I feel myself called upon (as having introduced the Baron into this country, and having, for a very long period, witnessed his great success in the operations of lithotripsy) to disabuse the public mind of an impression so undeservedly injurious to the reputation of a highly honourable gentleman, and skilful surgeon. At a very early moment I purpose entering fully into the subject, and I trust I shall effectually remove all the unwarrantable prejudices which have been attempted to be established by numerous individuals, who from want of sufficient observation and experience would prematurely condemn an operation, identifying the best feelings of humanity, in combination with much comparative security to the sufferers.

I have the honour to be, sir,

Your very obedient servant,

Anthony White.

Parliament-Street,

MEDICAL GAZETTE.

Saturday, April 16, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE GERMAN DIPLOMA SYSTEM.

HEIDELBERG AND ERLANGEN.

SOME observations which we made on the subject of the importation of German degrees, a few months since, have, we perceive, drawn forth reclamatory statements from Heidelberg and Erlangen. In a late number of the *Allgemeine Zeitung*, the heads of those Universities have published explanations, apologetical as well as recriminatory, with reference to the charges brought against them by us. Once for all, and *in limine*, we beg to say, that no remarks of ours were in the most remote degree intended to reflect disrespectfully on the learned individuals who compose the governing bodies of the Universities in question; for those individuals we have always entertained the highest respect: we merely censured—but that, too, "more in sorrow than in anger"—the exceeding facility with which they suffered themselves, as a body, to be imposed upon by strangers: and the principal brunt of our animadversions was directed against those who took advantage of their easiness for their own selfish purposes.

Had we any reason to believe that our statements on the occasion referred to were incorrect, we should be most willing to be set right, and cheerfully would we retract any proved misrepresentation. But, upon looking over the declarations of the Heidelberg and Erlangen authorities, we can only find matter in them confirmatory of our views. Of Heidelberg, be it remembered, we spoke cautiously, and with more reserve than of her learned sister. The University which includes in its list of professors the illustrious names of Tiedemann, Arnold, Chelius, Gmelin, and Muncke, would claim a respectful deference under any circumstances; and we rejoice to find that it is able, in a great measure, to exonerate itself from the imputation of too easy a bestowal of its diplomas.

We can make allowance for the tone in which Heidelberg offers its explanations; but come we to the facts. The records and archives of the medical faculty of Heidelberg, it is said, prove that only *eighteen* persons from Great Britain have obtained the degree of M.D. at that University within the last *ten* years; and that, of this number, *eleven* stood the test of the usual examinations,—which, it is added, cannot be so very superficial, inasmuch as several British candidates, who presented themselves to the test, were rejected, and others have thought proper to withdraw without attempting to try the ordeal. The inference from this candid statement is, that only *seven* diplomas have of late been given away by Heidelberg to British practitioners,—but on what terms, the heads of that University do not think proper to inform us.

The Erlangen faculty take up the matter in a very different temper from their brethren in Baden. They seem inclined to bluster, and make a grand display both of their principles and conduct. They express surprise and indignation at the charges brought against them in the MEDICAL GAZETTE, and proceed immediately to animadvert on the manner in which medical degrees are conferred in England; they describe the almost insurmountable obstacles which impede the procural of doctors' degrees by Roman catholics, dissenters, surgeons, and general practitioners, however able and celebrated,

who, in consequence of their exclusion from the English Universities, have been for years under the necessity of resorting to those of the continent, if desirous of practising as physicians! It is not denied that, *authorized by its laws*, the University has granted diplomas, without examination, to several members of medical and scientific societies in Great Britain, to teachers of the medical sciences, to persons of well-known reputation, and authors who had acquired celebrity by their works. Testimonials have been insisted on, such as certificates of competency from eminent professional persons. And such individuals, the declaration of the Erlangen faculty goes on to say, would not be considered unworthy of a diploma by any German University! Even in the course of last year, the University conferred degrees on several British practitioners whose works had obtained celebrity in Germany, and who had presented the required certificates of their qualification. The names of several persons are then given, by way of justifying this liberal mode of proceeding — but *such* names of *distinguished* authors, and *celebrated* practitioners!—in pity to all parties, we will suppress them. In conclusion, the medical faculty of Erlangen states, that it has done *no* prejudice either to German honour, German medicine, or to the character of the German Universities, and considers it much to be desired that other Universities of Europe should not grant degrees to persons *less* deserving!

We heartily concur in this last sentiment of the worthy Faculty, whatever difference of opinion we may entertain as to the prejudicing of German honour, character, &c. But let us ask, what have our Erlangen friends proved after all? Of what have they convinced the world by their public declaration? We really hesitate to express our free thoughts on their conduct, convinced as *we* now are of one fact, which we only half suspected before,—and that is, that however illustrious our German *savans* may be as men of books and men of science, as men of the world they are as simple as children, and as easily imposed upon by showy trifles. Have our statements been contradicted? Have they not been fully confirmed? We said that nothing was more easy than to procure an Erlangen degree. The certificate of three respectable professional men of known names we affirmed was sufficient, and that the depositing of *the money* with the appointed agent in London was an essential part of the process. In this respect, by the way, the faculty have shown themselves not quite *so* simple as might otherwise be thought. We mentioned that we knew the names of several who had availed themselves of this easy method of medical graduation, and thanks to the Erlangen declaration we now know of more. The system we denounced as *rapacious* (perhaps the term was too strong) on the part of the foreign University in question, and any thing but creditable to the individuals here, who by such means decorated themselves with tinsel finery and borrowed plumes. What, then, is there in the manifesto from Erlangen to warrant us to alter our opinions?

A word or two to this learned faculty of Erlangen, ere they again come forward to expose themselves. They talk in a lofty strain of their own liberality, and their desire to remedy our exclusiveness. Would it not be as well that they should endeavour to get acquainted with the evil to be remedied, before they venture to administer their specific for it? Let them learn, that with the exception of two Universities, to which nobody thinks of going for a medical education, there is no bar of prohibition elsewhere in these realms to prevent dissenters, Roman catholics, or surgeons (to use

the German classification), for proceeding regularly to degrees in medicine. But we have to inform them that there is not one of our Universities, or medical institutions, which can, "authorized by its laws," give away its *highest honours* for money, on the mere transmission of a certificate, and without a solicitation of the said honours in person. The force of opinion has for some time put down the abuse practised in certain Scottish Universities, and we believe it now remains for Erlangen alone, of all the medical establishments in Europe, to pursue the disgraceful system which we reprobate.

We trust, however, that these observations may have some effect in putting an end to the system. Our friends at Erlangen cannot take in ill part the suggestions which we offer: for we are sure that, on cool reflection, they cannot but see how they have been imposed upon, and nearly cheated out of their well-earned reputation. As to the worthy individuals here who long for *honours*, and have no objection to wear foreign mosaic, so as they may pass it off for sterling metal, we take some credit to ourselves for checking their absurd career. We rather think that in future they will find their market at Erlangen somewhat spoiled: they must now look well to their "works;" and if they have still the ambition of coming forth Doctors of Bavaria, they must, we fancy, have better certificates to produce than have hitherto been deemed sufficient.

SENTENCE ON A QUACK FOR MANSLAUGHTER.

SALMON, whose trial we reported last week, was brought up for sentence on Saturday, the 9th inst. The fine of 200*l*. to the King might, under other circumstances, be deemed considerable; but in the present flourishing state of the "Hygeian" concern, it is a mere trifle—as, indeed, was shewn by the immediate payment of the money, and the discharge of the prisoner. A public example ought to have been made of this man: were it only as the proxy of his master, he should have stood occasionally in the pillory, or sat in the stocks, with imprisonment and hard labour in the intervals of exhibition. We give the sentence as pronounced by the Recorder: it will be found to explain, in some degree, the opinions of Mr. Justice Pattison, some mistake, apparently, having gone abroad respecting their tenor.

"You have been convicted by a jury of your country, after a most patient investigation, and a most humane summing up of your case by the learned Judge, before whom you were tried, of the manslaughter of Mr. M'Kenzie; and the jury, in returning the verdict which they did, found that you had been guilty of gross want of skill and of gross rashness in administering large quantities of Morison's pills to an individual of the nature of whose disease you were ignorant. Some circumstances were proved in the course of your trial which were of a favourable description; for, from the evidence which was adduced, it appeared that you had, in very many cases, administered the same descriptions of medicine to other patients with great success. At the same time, however, it was also shown that you had represented yourself as a medical man, when, in fact, you were not in any way connected with the profession of medicine; but even if your representations on this head had been founded in truth, you would have been equally liable to punishment, had a verdict been returned against you similar to that which the jury have brought in in this case. Your conduct in this instance may be considered to be highly improper; for, when you found your mode of treatment to be unsuccessful, instead of desisting from it, you continued to administer large quantities of the same medicines which had already reduced your patient to a state of the greatest weakness, until at length he died. The learned Judge before whom your case was tried fully concurred in the verdict which was returned against you, and he has thought that, to meet the justice of the case, a very heavy fine should be inflicted on you, in order that other persons may be deterred from pursuing a similar line of conduct. The sentence of the Court, therefore, on you is, that you pay a fine of 200*l*. to the King, and that you be confined in His Majesty's gaol of Newgate until the same be paid. I think it proper, also, before you leave the dock, to caution you that, in the event of your be-

ing again found guilty of conduct of a similar description, the character of your offence will be very materially altered. I hope that the punishment which is now inflicted on you will deter others from rashly administering medicines, with the nature of which they are unacquainted, in large quantities, as the results may be fatal."

The prisoner then left the dock, and, the fine having been immediately paid, he was discharged out of custody.

MECHANICAL PHILOSOPHY AS APPLIED TO MEDICINE.

Abstract of Lecture Third: as delivered at the Aldersgate School,

By Dr. Birkbeck.

Dr. Birkbeck began by remarking, that a distinguished cultivator of organic science had compared the movements of the animal body to a vortex or whirlpool. In so far as floating matter was brought towards the centre by the revolution of the vortex, and, after having been tossed about for some time, was rejected to float as before, the resemblance of this matter to that which is introduced into the animal system might be admitted; but he observed, that a difference not adverted to by Cuvier occurs. The particles involved in the animal vortex become endowed with vital properties, and exercise new functions in consequence of this endowment; of which they only become divested, when they are expelled, again to make a part of the mass of common or brute matter. This change unceasingly proceeding during animal existence, we may designate by the words figuratively applied by Shakspeare to sleep: we may strictly call it, "the death of each day's life."

This ceaseless revolution of the matter from without, taking place in living organized tubes, changes, consequent upon pressure and motion, must occur. And it is not improbable, that the effect produced by certain organs, termed glands, in which the circulating fluid is subjected to pressure and motion through a great extent of vessel, often of extraordinary minuteness, is thus, at length, accomplished. The structure of the testicle, as commonly displayed, furnishes an excellent instance: the spermatic artery, always very small, becoming three hundred portions or bundles of sixteen feet each in length, and the two hundredth part of an inch in diameter; besides the length of the tortuous tube, the epididimus, in which, by means of the vasa brevia, they terminate, what may here exist, in addition to motion necessarily very slow, and pressure consequently very long continued, cannot be discovered. Whether they may be sufficient or not, it would be premature to decide.

It was next stated that the fluids, which were all contained in tubes, or areolæ, or cells, were subjected to hydraulic laws, or to corpuscular attraction, like ordinary fluids. That the condition of the tubes in animal structures did not remove them from the influence of these laws, was shewn by employing a flexible elastic tube, of considerable size, as a syphon, and with it emptying a vessel of water, with varying velocities, according to the mode in which it was bent. This, it was demonstrated, agreed with the syphon constructed with rigid materials.

The fluids in cells, it was asserted, were acted upon by the minute vessels proceeding from them, as capillary tubes, exactly similar to those which are formed of glass; the conditions, of course, under which each exert their action, varying proportionately the result.

For the distribution or circulation of the principal fluid, the blood, in the more perfect animals, the mammalia, for example, a beautiful hydraulic arrangement is provided. In the whale the apparatus is of great magnitude; the first tube, the aorta, being represented by Dr. Hunter, in his account of a dissection of this mighty animal, to be as large as the main-pipe of the old water-works at London Bridge. Through this pipe, with a prodigious velocity, ten or fifteen gallons of blood are driven by the heart at each contraction, constituting a force similar to that by which the water of the Thames was formerly distributed through this city. One important difference, however, is observable, it was mentioned, in the two hydraulic arrangements. In one the fluid is disposed of after distribution, and never returns; in the other, a second series of tubes is provided, by which the fluid, or a considerable part of it, is brought back to the impelling source. This constitutes what is usually termed the circulation, and one of the unavoidable appendages to the second series of tubes, the valves, or flood-gates, contributed materially to suggest and confirm the splendid discovery of Harvey, who, in the year 1620, made the most important addition to the knowledge of the animal economy that was ever achieved by one individual. The various forms of valves in the heart and blood-vessels were described, and shewn to be as strictly hydraulic instruments as those of a pump invented by

De la Hire, which was exhibited in action, or a common pump elucidated by a diagram, were admitted to be. A particular account was next given of the mode in which vessels are placed in relation to trunks and joints, and the provision which appears against casual pressure and friction, as well as against injury to important organs, from augmented impetus. An erroneous representation of the course of the arteries supplying the fingers, by Dr. Paley, in his admirable work on Natural Theology, was next corrected. "Sometimes the blood-vessels," says he, "proceed in channels, protected by stout parapets on each side; which last description is remarkable in the bones of the fingers, these being hollowed out on the under side like a scoop, and with such a concavity that the finger may be cut across to the bone, without hurting the artery which runs along it." Now, as the skeleton hand proved, there is neither parapet nor concavity, but as the injected hand shewed, a vessel for supplying each finger, divided into two branches at the first phalanx, and these branches proceeding securely along the sides of the fingers. The peculiarities of the cerebral circulation were then insisted upon, and the results, physiological and pathological, arising from the cavity of the cranium being air-tight, and the brain and blood being, as to all practical effect, incompressible, were specially displayed. To assist the comprehension of these inferences by Drs. Monro, Clutterbuck, and others, the hydaulic press of Bramah was referred to; and the improbability of an increased quantity of blood at any time existing within the cranium, without some proportionate abstraction, and the certainty of increased pressure, where what is called increased determination of blood to the head occurs, lead to the strong recommendation of the free use of the lancet in affections of the head, instead of the partial abstraction of blood topically, as it is unwarrantably called, by leeches and cupping.

Dr. Birkbeck then proceeded to speak in detail of the structure and offices of another class of vessels supporting, in the form of introduction and expulsion, a species of circulation. The lacteals, the introducing, and the absorbents, the removing, were fully described; and considerable attention bestowed upon the formation and function of the villous processes of the internal coat of the intestines, and the mouths of the ordinary absorbents. In illustration of this subject, the elevating influence of glass planes and glass tubes, of very small diameters, was exhibited; and the manner in which this, the first step in absorption, the attractive step, conduces to the performance of the important animal function, was fully displayed. Of this part, as well as of some others touched upon in this lecture, a more complete development, it was stated, would appear, when, in the lecture succeeding, the subject of pneumatics, in relation to the animal economy, was specially discussed.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, April 12, 1836.

H. Earle, Esq., F.R.S., President, in the Chair.

There was a very full attendance of the Fellows and their friends this evening. The following is an abstract of the first paper which was read: it was entitled—

Case of Congenital Dislocation, or Displacement, of the Hips. By John North, F.L.S., Lecturer on Midwifery, and the Diseases of Women and Children, at the Westminster School of Medicine.

The author had hoped, when the subject of this case came under his care, to have been the first English writer to place on record an example of the kind; but he afterwards learnt that a similar case had already been published in the Dublin Journal, for September, 1835. Mr. North confessed, that for all the knowledge he possessed on the subject, he was indebted to a paper by M. Dupuytren, in the "Repertoire Gén. d'Anat," which paper he read immediately after it was published, and the importance as well as novelty of its contents especially attracted his attention, because he believed he had seen, both in public and private practice, this particular kind of congenital displacement mistaken for disease of the hip-joint, and that in consequence of this error a long-continued, painful, and altogether useless plan of treatment, had been adopted. According to M. Dupuytren, the displacement consists in a transposition of the head of the femur, from the acetabulum into the external iliac fossa. It exists from birth, and appears to result from a want of depth in the acetabulum, rather than from any accident or disease.

In September last Mr. North was requested to see a child about three years old, which was thought to be labouring under disease of the hip joint, for which leeches in abundance, blisters, and caustic issues, had been very freely and very fruit-

lessly employed. From its birth to the age of about a year, the child appeared in good health, and nothing remarkable about its limbs attracted the attention of the friends or medical attendant. When about a year old, the mother "thought the shape of the hips rather odd," whenever the child was placed with its feet on the ground; but as she appeared quite free from pain, and in good health, medical advice was not deemed necessary. For some time after the age when children usually begin to walk, the mother found that her little girl was quite unable to stand upon her feet; this was at first attributed to her being backward in walking, and therefore was neglected. At two years of age the child was still unable to stand or walk for more than a minute; and even this slight exertion was effected with much effort and difficulty. The "odd shape" of the hips and thighs was now more evident, and a village surgeon was consulted. The case was determined to be one of "a beginning of white swelling in both hips." The child was accordingly confined to bed, and went through the usual routine of leeches, blisters, and issues; very spare diet was recommended, from the apprehension of inflammation in or about the hip-joints. From this discipline, which was continued with different degrees of activity for three or four months, the health of the child declined, and she became much emaciated. The "odd appearance" of the hips and thighs was rather increased than diminished, and the child was still unable to stand or walk. The mother therefore determined "to have done with doctoring, and to trust to nature" and nourishing food.

The child soon recovered her health, and about six months after the discontinuance of all medical treatment Mr. North saw her. Upon extending the limbs, he found them of equal length, and natural in appearance; the knees, however, being a little turned inwards. No pain was given by pressure, or by quickly moving the limbs in any direction; no tumefaction; no appearance of inflammation. She was placed on her feet, naked, and instantly the description given by Dupuytren of congenital displacement of the hips occurred to the author. She was raised upon her feet, with her mother's hands under the armpits, and the moment she rested her feet on the ground, the nature of the case was evident. The knees struck together; the thighs were shortened; and the head of the femur on each side could be felt raised upwards on the dorsum of the ilium, towards the crista. When the child attempted to move forwards, the appearances so well described by Dupuytren immediately resulted. She seemed to require much preparation for the act of progression. One foot was very deliberately raised from the ground, her body sinking towards the side that was to support its weight; and as she walked, or rather waddled forwards, the head of the femur upon which she rested could be felt, and, indeed, seen, rising upon the dorsum of the ilium; the limb that moved forwards came to the ground with a feeble jerk, and when in its turn it had to support the superincumbent weight, the head of the femur on that side was raised in the same manner. The child was soon tired, but suffered no pain. She was put to bed, and again examined. Mr. North now found, as he expected, that he could, without any difficulty, and without giving any pain, lengthen the thighs by drawing them gently downwards, or shorten them by pushing them gently upwards. Judging from the alternate elevation and depression of the trochanters which were thus produced, the head of the femur on each side appeared to move more than an inch upwards and downwards.

The nature of the infirmity could not be doubted. It was certain, from the history of the case from its commencement, that no disease had existed. It was equally clear, from the appearances, that the acetabulum on each side was deficient in depth, and did not retain the head of the femur. Mr. North stated the irremediable nature of the case to the friends, and advised them not to permit any painful treatment. He recommended them to adopt the plan suggested by Dupuytren: to apply a well-padded belt around the pelvis, so as to prevent the head of the thigh-bones from rising on the ilium when the child attempted to walk. By this means she was enabled to walk with more facility and firmness, and without any pain, when she became accustomed to the bandage. The child died about three months ago of hooping-cough: the author regretted that he could not examine the body, but expressed his belief that, even without the evidence of dissection, no doubt could exist as to the nature of the case.

Mr. North then gave some account of the paper of Dr. Hutton, in the Dublin Journal. Dr. H.'s patient—an idiot—died of inflammation of the larynx. He had been lame from infancy, and the hip-joints bore the marks of leeches, issues, &c. Upon dissection, Dr. Hutton found an imperfect formation of the acetabulum on each side, which accounted for the displacement of the femurs that had existed during life. There were no marks of inflammation or disease in the joint.

According to M. Dupuytren, the subject of congenital dislocation is especi-

ally important in reference to diagnosis; for, as it presents all the ordinary signs of luxation of the hips, which is often consecutive to disease of the joint, it always has been confounded with it, and submitted to the same treatment. He relates several cases which were maltreated from this mistake. The diagnosis is, however, easy, by attending to the commencement of the lameness, and the general history of the case.

In the few cases M. Dupuytren had an opportunity of examining after death, he found the following appearances. The muscles attached above and below the acetabulum were all dragged towards the crista ilii. Some of these muscles were well developed; others small and shrunk, and had lost all appearance of muscular tissue. The acetabulum was either entirely wanting, or the only vestige of it was a small irregular osseous projection, without any trace of cartilage, synovial capsule, or fibrous margin. In two or three subjects the round ligament was lengthened and flattened. The ligament was lodged in a cavity analogous to that which is developed around the head of the femur in accidental and unreduced luxations of the bone upwards and outwards.

With respect to treatment, cure is hopeless and impossible; nor can any very efficacious palliative means be adopted. Extension of the limbs is useless; repose, in a sitting posture, is necessary. Any avocation which would demand exercise would be improper for persons thus afflicted. But as they cannot be condemned to constant rest, something must be done to diminish the inconvenience they experience when they stand or walk. The cold bath is recommended, and a soft well-padded girdle to be worn round the waist to fix the trochanters, and keep them from rising upwards. M. Dupuytren met with about 25 cases of this displacement in 20 years, and it is curious that all but 3 or 4 were females. In all but 2, b th femurs were luxated.

In conclusion, Mr. North observed that Dupuytren was by no means the first who noticed this disorder. Hippocrates, in his tract De Articulis, had rather indefinitely referred to it; and Paletta, *De claudicatione congenita*, described it clearly.

Mr. Langstaff offered a remark or two expressive of certain doubts which he entertained as to the nature of the disorder. He objected to the term dislocation; thought M. Dupuytren's description ambiguous; and was rather inclined to believe that in the cases mentioned, the child might in labour have presented by the feet, and that the limbs were dislocated by pulling at them!

Mr. North was quite willing to accept any other term that Mr. L. might suggest, instead of dislocation, but he thought the explanation offered—of dislocation caused by pulling at the feet—was quite imaginary. It could hardly be supposed that in so many cases such malpractice could have been adopted; and he doubted the possibility of inflicting such an injury by any degree of force that the most ignorant practitioner could apply.

The President said he felt much interested in the subject of Mr. North's excellent paper, and related a case in point, of a girl 11 years of age, who had been under his care: he was convinced that she laboured under congenital malformation. However, since he discontinued his attendance on her, he was informed that she had been placed under the care of a practitioner who was trying the method of active extension: it was boasted that the hips had already been drawn down *three inches!*

A short paper was then read by the Secretary, *On Dislocation of the Femur*, by Mr Travers, Jun.; after which the Society adjourned.

MEDICAL EDUCATION IN IRELAND.

SCHOOL OF PHYSIC.

To the Editor of the Medical Gazette.

Sir,

Dr. Lendrick's second letter, addressed to you, contains not facts, but notions and vain assertions, which it would be a waste of time to discuss.

It is not to be denied that the Board of Trinity College have ordered me to teach anatomy and surgery as *one* course, and that this kind of instruction is not considered sufficient in any other medical establishment, or school, in the United Kingdom. These facts are already before the public; with respect to which, and their consequences to the School of Physic in Ireland, there will, I am satisfied, with all intelligent and impartial men, be but one opinion. I shall therefore not wish, probably, to occupy the pages of your journal further on this subject.

I am, sir,
Your very obedient servant,
James Macartney.

Dublin, April 12, 1836.

[Here this controversy must close; or, if *we* may have the last word, it is to say that we have seen no reason assigned, to warrant us in changing our opinions as we stated them in the outset. See last vol. p. 819.—Ed. Gaz.]

COLLEGE OF SURGEONS.

RECOGNIZED TEACHERS OF ANATOMY.

———

(For the Medical Gazette.)

The Council of the Royal College of Surgeons deem it essential that teachers of anatomy should be provided with the preparations of parts mentioned in the following schedule, intended to comprise those preserved, injected, or otherwise prepared structures which cannot be adequately demonstrated in the recent subject.

1. Artificial skeletons, male and female. 2. The several bones of the skeleton, including the separated bones of the cranium. 3. Sections of the cranium. 4. Preparations showing the structure and growth of bone. 5 The component structures of the various joints. 6. The deciduous and permanent teeth, their structure and formation. 7. The mouth, salivary glands, fauces, and other parts concerned in deglutition. 8. The organs of digestion and their appendages; exhibiting the structure of the alimentary canal, of the glandular and other parts concerned in the digestive process. 9. The thoracic duct, the lacteals, and the other absorbent vessels, with their glands. 10. The heart, exhibiting its structure in the adult and fœtal states; and the parts concerned in the circulation of the fœtus. 11. The blood-vessels, their structure, arrangement, and distribution. 12. The larynx, the trachea, and the lungs, with the distribution of the air-tubes and the blood-vessels. 13. The brain and spinal cord, with their membranes. 14. The nerves, their origin, structure, and distribution. 15. The organs of the senses:—1. Of sight: the globe of the eye, its component textures, the lachrymal apparatus, and its other appendages. 2. Of hearing: the various parts comprised in its external, middle, and internal divisions. 3. Of taste: the tongue, its nerves and papillæ. 4. Of smell: the nasal chambers, the communicating sinuses, and their lining membranes. 5. Of touch: the peculiar conformation of the skin instrumental thereto, with the structure of the common integuments and their appendages.—16. The urinary organs, showing the structure of the kidney and ureters, of the bladder, the urethra, and Cowper's glands. 17. The male organs of generation, exhibiting the structure of the testis and vas deferens, of the vesiculæ seminales, of the prostate gland, and of the penis. 18. The female organs of generation in the unimpregnated and gravid state. 19. The peculiarities of the fœtus.

It is expected that teachers of surgery should have the means of illustrating, by suitable preparations, those points in pathology and practice which are treated of in surgical lectures.

Edmund Belfour, *Sec.*

March 15, 1836.

MEDICAL ATTENDANCE ON THE SICK POOR.

PETITION FROM THE PRACTITIONERS OF SURREY.

———

To the Editor of the Medical Gazette.

Sir,

I beg to transmit to you, for insertion in the Medical Gazette, a copy of the Petition from the medical men of Surrey, which was presented by Lord Eastnor on the 29th March.—I am, sir,

Your very obedient servant,

Peter Martin.

Reigate, April 13, 1836.

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament assembled.

The humble Petition of the undersigned Practitioners in Medicine and Surgery, residing in the County of Surrey,

Sheweth,

That your petitioners, in common with the great body of medical practitioners, have long felt the evil resulting from the practice of contracting, more especially by tender, for the medical attendance on the sick poor.

That on a change of system being generally adopted in the administration of the poor laws, it was the expectation of your petitioners, that a practice at once injurious to the poor, and derogatory to the profession, would have been discontinued.

That your petitioners have seen, with regret, that the Poor-law Commissioners have taken no steps to remove the evils complained of; which have, on the contrary, increased under the new system.

That although the Commissioners have declared it not to be obligatory on Boards of Guardians to accept the lowest tender that may be offered, yet it is notorious that such is generally the practice.

That in providing for the care of the sick poor, the only guarantee which Boards of Guardians can possess for the proper performance of that duty, will be found to consist in the appointment of men of known respectability and experience; an

object not likely to be attained by the present system.

That the difficulty of affording medical assistance to the poor is much increased by the division of Unions into very large districts, and the appointment of a less number of medical officers than under the old system.

That the regulation by which the relieving officer is constituted the judge, as to whether the indisposition of a pauper is sufficiently serious to require medical relief, is likely to be very injurious to the health of the poor, and consequently to increase unnecessarily the labour of the attendant.

That your petitioners are far from wishing their interests to be considered in opposition to those of the rate-payers. On the contrary, they are firmly convinced, that economy in the parochial expenditure will be promoted by the furnishing of good and sufficient attendance to sick paupers; and they are further convinced, that this object is not likely to be generally attained, when rates of remuneration are offered so utterly inadequate to the skill and attention required.

Your petitioners therefore pray that your Honourable House will be pleased to appoint a committee to inquire into the present system of affording medical relief to sick paupers; and into the propriety of adopting any change in the same.

And your petitioners will ever pray.

[With 64 signatures.]

THE LATE MR. W. DOBSON.

(From a Correspondent.)

Died, on the 10th of March, at his house, Princes-Street, in the 29th year of his age, William Dobson, Esq., M.R.C.S., Lecturer on Comparative Anatomy at the Westminster School of Medicine.

Mr. Dobson commenced his brief but creditable career in the promulgation of anatomical science in the winter of 1829, during which period, and the winter of 1830, he lectured on anatomy at the school of medicine in Leeds, established by the late Mr. Charles Turner Thackrah. He afterwards came to London. In October last he commenced teaching comparative anatomy, but had delivered only two lectures on the subject, when he was seized with the disease (consumption) which terminated his life. Mr. Dobson has left behind him several works on anatomy, which it is probable will ere long be published. We regret to learn that he has left a widow and two children totally unprovided for.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

April 14, 1836.

Francis Morgan Walker, Chesterfield, Derbyshire.
Robert Rivers, Ipswich.
John Charles Langmore, Finsbury-square.
Joseph Teale, Leeds.
William Pierce Jones, Holywell, Flintshire.
George Jessett, Horncastle, Lincolnshire.
Henry Dibble Chester, Redruth, Cornwall.
Josiah Johnson Elletson.
James Acland de la Hooke, Ilchester, Northamptonshire.
George Bailey Snow, Lincoln.

LECTURES

ON

MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

BY JON. PEREIRA, ESQ., F.L.S.

LECTURE XXX.

IN this lecture I have to continue the account of the preparations of *sodium*.

Bi-borate of Soda.

History and synonymes.—Pliny describes a substance under the name of *chrysocolla*, which is usually thought to be the borate of soda. But the word *baurach*, or *borax*, first occurs in the writings of Geber: hence this term is probably of Arabic origin, though some derive it from the Greek, *βορος*, voracious, or gluttonous. By modern chemists the salt has been termed *bi-borate*, *borate*, or *sub-borate* of soda.

Native state.—It is found, dissolved, in the water of certain lakes; more particularly in Persia and Thibet.

Preparation.—Borax is obtained in two ways:—1st, by refining native borax; 2dly, by saturating native boracic acid with soda.

(*a.*) *By refining native or crude borax.*—About fifteen days' journey north from Teeshoo Lomboo, in Thibet, is a lake, said to be about twenty miles in circumference, and supplied by brackish springs rising from the bottom of the lake itself. In consequence of its high situation, during a part of the year this lake is frozen over. The water of it contains, in solution, both common salt and borax. The latter crystallizes on the edges and shallows of the lake, and is taken up in large masses, which are broken and dried.

It is imported under the name of *tincal* or *crude borax*, in the form of flattened six-sided prisms, coloured with a greasy unctuous substance, said, by Vauquelin, to be a fatty matter, saponified by soda; the colour is yellowish, bluish, or greenish. Mojon states that the greenish grey matter which surrounds some kinds of rough borax, contains native boron. Various methods have been contrived for refining borax; some calcine, to destroy the fatty matter, others wash with an alkaline solution (soda or lime), and then dissolve and crystallize.

(*b.*) *By saturating native boracic acid.*—In the year 1776, Messrs. Hoefer and Mascagni discovered boracic acid in the Lagoni of Tuscany, in a state of efflorescence, and also in solution in the waters with which the soil is impregnated. From the soil is constantly evolved aqueous vapour, impregnated with boracic acid and sulphuretted hydrogen; formed, as it is supposed, by the action of water on sulphuret of boron, contained in the interior of the earth,—by which part of the water is decomposed, the oxygen acidifies the boron, while the hydrogen forms sulphuretted hydrogen with the sulphur, and the heat evolved causes the formation of some aqueous vapour. By washing the mud surrounding the *fumaroles*, or craters, decanting the liquor, and evaporating, *rough boracic acid* is obtained; or, as it is frequently termed, *Tuscan boracic acid*. To form borax from this, a solution of the subcarbonate (carbonate) of soda is saturated with the rough acid: effervescence takes place, and borax is formed.

Properties.—As met with in commerce, borax is a white salt, in irregular crystalline pieces, the primary form of which is usually said to be the oblique rhombic prism, but from the measurements given by Dr. Thomson it would appear to be a doubly oblique prism. The taste is feebly

saline, sweetish, and alkaline: by exposure to the air the salt becomes white; when heated, it melts in its own water of crystallization, swells up, and forms a light, white, and porous substance, called *borax usta* seu *calcinata*, which, by a stronger heat, fuses into a glass.

Composition.—Borax is composed of—

	Thomson.		Berzelius.
Boracic acid..	2 atoms or = 48	..	2 atoms or = 69·8
Soda	1 atom or = 32	..	1 atom or = 31·3
Water	8 atoms or = 72	..	10 atoms or = 90·0
	152		191·1

By a particular management of the crystallizing process, Payen has obtained a borax in octahedral crystals (called *octahedral borax*) with only half the above quantity of water of crystallization.

Characteristics. — Borax may be recognised by the following characters: it reddens turmeric paper; it fuses before the blowpipe into a glass, which may be readily tinged by various metallic solutions,—thus, rose red by chloride of gold, and blue by solutions of cobalt; if a few drops of sulphuric acid be added to powdered borax, and then some spirit of wine, the latter will, when fired, burn with a green-coloured flame; lastly, if to a strong hot solution of borax, sulphuric acid be added, boracic acid will be deposited in crystals as the liquid cools. The tests now mentioned, for the most part only, prove the salt to be a borate: the nature of the base is determinable by the tests for soda already mentioned.

Physiological effects.—The local effects of borax are those of a mild irritant: applied to sores, it excites temporary pain and heat, and swallowed in large doses is said to vomit. Various remote effects have been attributed to it: at one time it was regarded as a subsalt, and its supposed excess of alkali was thought to render its action similar to soda, and thus, in some old authors, we find it classed among the antacids. When Homberg asserted, that boracic acid was a sedative substance, borax was supposed to partake of the same operation. A specific action on the uterus has also been ascribed to it; and thus borax is said, by some authors, to be emmenagogue, to facilitate parturition, to diminish the pain of accouchement, and to favour the expulsion of the placenta and lochia. The correctness of these statements is not admitted—at least in this country. Another effect attributed to borax is diuresis; and as Wohler and Stehberger have found that this salt passes off unchanged by the urine, the statement is very probable. On the whole, we may regard borax as a mild refrigerant.

Uses.—It is principally employed as a local application in aphtha, and ulcerations of the mouth, in which it is said to act as a detergent The *mellite of borax* is by far the most eligible form of employing it; it consists of one drachm of powdered borax, mixed with an ounce of clarified honey. In various skin diseases, borax has been applied with benefit: dissolved in rose water, it is a frequently-used cosmetic, and has been employed with advantage in *pityriasis versicolor* (called *liver-spots*, or *chloasma*.) As an injection in gonorrhœa and leucorrhœa, a solution of this salt has been found occasionally successful. Lastly, in the form of ointment, it has been applied to inflamed and painful hæmorrhoidal tumors.

Tartrate of Soda.

This salt is never met with in the shops, but is formed extemporaneously by mixing tartaric acid with the carbonate or sesquicarbonate of soda, and, therefore, is procured in the mixing of *soda powders*. The proportions for making this salt are as follows:—

15 grains of tartaric acid will saturate $\left\{\begin{array}{l}28\frac{3}{4}\text{ grains of } \textit{sesqui-carbonate} \text{ soda (sold in the shops as the carbonate).}\\ 16\frac{2}{3}\text{ grains of } \textit{carbonate} \text{ (subcarbonate of the shops).}\end{array}\right.$

It is a very mild aperient and diuretic; its action being similar to the other vegetable salts already noticed.

Potash tartrate of Soda.

History and synonymes. — This salt was discovered by Seignette, an apothecary at Rochelle, in 1672, and hence its name, *salt of Seignette*, or *Rochelle salt*. In the Pharmacopœia it is termed *soda tartarizata.*

Preparation.—It is prepared by saturating the bitartrate of potash with the subcarbonate (carbonate) of soda. In the Pharmacopœia the proportions are two pounds of the bitartrate, and twenty ounces of the subcarbonate. The excess of acid of the bitartrate saturates the soda of the subcarbonate, while the carbonic acid of the latter is disengaged.

Properties.—The primary form of the

crystals is the right rhombic prism; but, curiously enough, the crystals are sometimes produced in halves. The taste of this salt is mildly saline, and somewhat bitter. Exposed to the air it effloresces slightly; when heated, it gives out part of its water, melts, and at a stronger heat is decomposed. It is soluble in two and a half times its weight of cold water.

Composition.—This salt consists of—

1 atom of tartrate of potash,	114
1 atom of tartrate of soda ..	98
10 atoms of water, 9 × 10 ..	90
	302

Its formula, therefore, is $\dot{K}\,\overline{T} + \dot{N}\,\overline{T} + 10\,\dot{H}$.

Characteristic tests.—This salt is easily recognized by the form of its crystals. When heated it is decomposed, gives out an odour of caramel, and is converted into charcoal and the carbonates of potash and soda. By the addition of hydrochloric acid, these carbonates are converted into chlorides; and, by the chloride of platinum, the chloride of potassium may be separated from the chloride of sodium. A solution of the potash-tartrate of soda gives a white precipitate (*soda tartrate of barium* or of *calcium*) on the addition of chloride of barium or of calcium; while perchloric and tartaric acids, and the chloride of platinum, readily detect the potash present by the precipitates they occasion.

Physiological effects.—It is a mild, laxative, cooling salt, very analogous in its effects to the tartrate of potash. Like the other vegetable alkaline salts, it undergoes partial decomposition in the system, and is converted into the carbonate which is found in the urine.

Use.—It is a commonly employed mild aperient, and is frequently taken in an effervescent form under the name of *Seidlitz powders*, which, however, have no resemblance to the salts obtained from the Seidlitz waters. Seidlitz powders are thus prepared: two scruples of the sesquicarbonate of soda (carbonate of the shops) are mixed with two drachms of tartarized soda; these are the ingredients for one powder (usually sold in white paper), which is to be dissolved in half a pint of water; and to the solution are to be added thirty-five grains of powdered tartaric acid (commonly sold in blue paper): effervescence takes place, and we obtain a mixture of the *potash—tartrate of soda*, and the *simple tartrate of soda*.

Soap.

History.—The manufacture of soap was very anciently known, for this substance is mentioned in the Old Testament; and in the excavations made at Pompeii, a complete soap-boiler's shop was discovered, with the soap still perfect, though it had been manufactured for more than 1700 years.

Nature.—Soaps are to be regarded as alkaline salts, formed by the action of alkaline bases on fatty or resinous bodies. At one time it was supposed that they were mere compounds of fat or resin, and of alkali, but it is now known that in the process by which they are procured, the fatty body employed undergoes certain changes, by which two or three fixed fatty acids are produced—namely, the oleic, margaric, and stearic acids; these uniting with the bases (potash or soda) employed, form oleates, margarates, and stearates.

Having already, in a former part of the course*, noticed the products of saponification, it is unnecessary that I should here enter farther into the subject. Soaps, then, you will observe, are to be considered as mixtures of the *oleates*, *margarates*, and *stearates* of some base (usually *potash* or *soda*). When potash is used, the resulting salt is called *soft soap*, the common kind of which is made with fish-oil. *Hard soap* contains soda as the alkali, and is of various kinds: thus *yellow soap* is made from rosin and soda; *mottled soap*, of kitchen stuff and soda; *curd soap*, of white tallow and soda; and *Castile soap*, of olive oil and soda. In the London Pharmacopœia, the officinal soaps are *soft soap* and *Castile soap*.

Physiological effects.—The operation of soap on the system is analogous to that of the alkalies, only that it is much milder even than the carbonated alkalies, and, therefore, may be administered internally without danger of any violent local action on the gastro intestinal membrane. The alkali of the soap will, however, neutralize the free acid of the stomach, and the fatty acids of the soap will be set free. By continued use it disturbs digestion, disorders the appetite, and in fact gives rise to all the constitutional effects already described as produced by the continued employment of the alkalies: it increases the secretion of the urine, and probably modifies the quality of this fluid, just as the vegetable alkaline salts do. In large doses it is purgative.

Uses.—Soap is employed in medicine for various purposes. Dissolved in spirit of wine, with camphor and oil of rosemary, it forms a very useful stimulating application (*linimentum saponis compositum*), in local pains, bruises, rheumatism, &c. It may be swallowed as an antacid: thus in poisoning by the mineral acids, a strong solution of soap is a valuable antidote, since it effectually neutralizes the poison, without itself being very irritant; so, also,

* MEDICAL GAZETTE, vol. xvii. pp. 323 and 678.

to neutralize an excessive secretion of acid in dyspeptic complaints. In those forms of lithiasis in which lithic acid, or the lithates, prevail, soap is useful in preventing the formation of these bodies, just as the alkalies are. On account of its easy solubility, it is often used in combination with other medicines, in order to render them more soluble, or to give a proper consistence to various substances for the making of pills. Thus we have in the Pharmacopœia several pills which contain soap as one of their ingredients. Injections into the rectum of a strong solution of soap are sometimes made, in order to dissolve hardened fæces. Although, when soap is swallowed in full doses, it acts slightly on the bowels, yet it is rarely employed as a purgative merely, though it has been recommended in liver complaints, habitual costiveness, &c.

Chloride of Sodium.

History and synonymes.—As this salt is a necessary and indispensable seasoning to our food, it doubtless must have been known to the first individuals of our race. It has received various names, such as *common salt*, *culinary salt*, *marine* or *sea salt*, and *muriate of soda*.

Native state.—It occurs in both kingdoms of nature: thus sea and most mineral waters contain it. We meet with it in rocks of various ages: thus the constant accumulation of salt which is taking place in the inland lakes, may be mentioned as an instance of the occurrence of it in the the modern or *alluvial group*; and proceeding to other older groups, in the order of their age, I may mention the salt deposit at Wielicka, near Cracow, occurring in the *supra-cretaceous group*: the immense masses of salt at Cordova, in Spain, in the *cretaceous group*; the salt which occurs in the Lias, in Switzerland, in the *oolitic group*; the beds of salt in Cheshire and Worcester, in the *red sandstone group*; the salt springs which occur in this country, in the *carboniferous group*, and the brine springs in the old transition slate rocks of the *grauwacke formation*, in the United States. Most, if not all, geologists agree that these deposits of salt must have been once in a state of solution.

In the organized kingdom also, we meet with chloride of sodium: thus the blood and urine of man contain it.

Preparation.—The common salt of commerce is sometimes obtained by purifying native or rock salt; sometimes by the evaporation of water of brine springs; and lastly, sometimes from sea water.

1. *Purification of native salt.*—This native salt is usually denominated *rock* or *fossil salt*, or *sal gemmæ*. The English salt-mines occur in three counties—in Cheshire, at Northwich, Middlewich, and Nantwich; in Staffordshire, at Shirleywich; and in Worcestershire, at Droitwich. In Cheshire, the salt constitutes two beds, varying in thickness from 4 to 130 feet, and separated from each other by a bed of clay, 10 or 12 feet thick; the first bed of salt beginning at about 30 yards from the surface. It is for the most part of a reddish colour, but it is also met with in transparent colourless masses. In commerce it is termed *Prussian rock*, and is largely exported for purification. It is seldom met with sufficiently pure for use. According to Dr. Henry's analysis, it consists of

Chloride of sodium	983·2500
Sulphate of lime..........	6·5000
Chloride of magnesia......	0·1875
Chloride of calcium	0·0625
Insoluble matter	10·0000
	1000·0000

Bromine (probably combined with magnesium) has been found in the brine of springs, and hence doubtless exists in fossil salt. Fuchs has discovered iodine in the rock salt of the Tyrol.

Rock salt may be purified by dissolving in water and crystallizing; various substances (as glue, blood, butter, flour, alum, albumen, &c.) being added to the water, to promote the separation of the earthy matters.

2. *By the evaporation of brine springs.*—This is the method now adopted in this country. Brine springs are met with both above and below the level of the beds of rock salt. According to Dr. Holland, those of Cheshire contain from 21 to 27 per cent. of salt; the latter quantity (according to this same writer) constituting a saturated solution. The formation of these springs is easily accounted for: rain-water sinks through the earth covering the beds of rock salt, and at last arrives at the salt itself, where it rests, and forms a saturated solution. The brine-springs below the beds of salt, doubtless arise from the percolation of the water holding in solution salt.

The brine is pumped up by steam power into cisterns, or reservoirs; from which it is drawn when wanted, through wooden pipes, into the evaporating pan, which is made of cast iron. When the brine is not quite saturated, a little Prussian rock is added, to strengthen it. Various substances, as before mentioned, are put into the brine, with the view of causing the separation of the earthy matters: the impurities separate in the form of scum and sediment, the latter being termed *scale*, or *panscratch*. As all parts of the pan are not equally heated, the crystalli-

zation of the salt takes place at various times; and thus, in the same pan, the grains or crystals vary considerably in size. The large or coarse-grained salt constitute the *bay* and *fishery salts*; while *butter salt*, and *stoved*, *lump*, or *basket salt*, are small-grained salts.

3. *From sea-water.*—In various parts of the world, salt is obtained from sea-water: the particular mode of extracting it, however, varies according to circumstances. In warm countries, the salt (termed *bay salt*) is procured from sea-water by *solar evaporation*. [A plan of the salt-marshes of France was here shown and described]. In cold countries, *congelation* is resorted to, as a means of concentrating sea-water; for when a weak saline solution is exposed to great cold, it separates into two parts; one almost pure water, which freezes, and the other which remains liquid, and contains the larger proportion of salt. The ice being removed, the concentrated solution is afterwards evaporated, so as to obtain the salt. Another method of concentrating sea-water, or other saline solutions, is by *graduating houses*—that is, skeletons of houses, in which the water is pumped up, and allowed to fall on heaps of brushwood, thorns, &c.; by which it is divided and agitated with the air, and evaporation promoted. The further concentration is effected by artificial heat.

Properties.—It crystallizes in cubes, and in octahedrons: sometimes we meet with it in hollow four-sided pyramids, the sides of which are not planes, but like a flight of stairs. When heated, the salt decrepitates, (more especially the coarse-grained, or bay salt) in consequence of the conversion into steam of the particles of water which are mechanically lodged between the plates of the crystals; it melts at a red heat, and at a still higher temperature is volatilized. According to Gay-Lussac, 100 parts of water at 57° dissolve 36 parts of salt; and at 32°, the quantity dissolved is rather larger.

Impurities.—The salt met with in commerce in this country is sufficiently pure for all dietetical and therapeutical purposes; and its low price is a sufficient guarantee against its adulteration. In France, however, serious accidents have happened in consequence of the use of sophisticated salt.

Composition.—The crystals of this salt contain water, lodged mechanically between the plates of the crystal, but no combined water: they consist of

1 atom chlorine....	36
1 atom sodium	24
	60

Its formula, therefore, is N Chl.

Characteristic tests.—The yellow tinge which it communicates to the flame of alcohol, shews it to be a soda salt. Nitrate of silver readily detects the chlorine, by producing a white precipitate soluble in ammonia, and insoluble in nitric acid.

Physiological effects.—In discussing the medicinal effects and uses of salt, we must not overlook its dietetical properties. We all know that it is largely employed as a seasoning to our food, and appears to be indispensable to the preservation of health and life, though the quantity taken by different individuals is exceedingly various, some having a much greater relish for it than others. What may be its particular use in the animal economy, we know not. It is an essential constituent of the blood, and is found in several of the secretions; for example, the urine, the bile, the tears, &c. Doubtless, the free hydrochloric acid of the stomach is obtained by the decomposition of the common salt, as is also the soda found in the blood and bile.

Considered in a therapeutical point of view, chloride of sodium is to be regarded in its local operation as an irritant. Taken into the stomach in large quantity, (as a table spoonful) it excites vomiting, while thrown into the large intestines, it causes purging. In moderate quantities, we regard it as promoting digestion and assimilation, and assisting to keep the bowels regular. It has been found to be an efficacious anthelmintic, and it is said that those who take little or no salt with their food are very subject to intestinal worms. Dr. Paris tells us that Lord Somerville, in his address to the Board of Agriculture, states that the ancient laws of Holland "ordained men to be kept on bread alone, *unmixed with salt*, as the severest punishment that could be inflicted upon them in their moist climate; the effect was horrible: these wretched criminals are said to have been *devoured by worms* engendered in their own stomachs." In further proof of the anthelmintic powers of salt, a case published by Mr. Marshall, in the 39th vol. of the Medical and Physical Journal, may be referred to. A lady who had a natural aversion to salt, was most dreadfully affected with worms during the whole of her life.

Every one knows that the use of much salt causes thirst. The continued immoderate employment of it is said to excite scurvy. Moderate quantities of it seem to produce tonic effects on the system.

Uses.—(*a.*) *Internally*—salt is sometimes useful as an *emetic*; for example, in narcotic poisoning, in the absence of other more useful caustics, one or two table spoonfuls of salt may be taken in a tumblerful of water. So also in malignant cholera it is

often preferred as a vomit to other agents. We rarely employ it as a *purgative*, though its repeated use must be attended with this effect. As a chemical *antidote* it is administered in poisoning by nitrate of silver: the chloride of silver, which is formed being, according to Orfila, inert. As an *anthelmintic* it has been administered with advantage. In scrofulous subjects it has sometimes been employed as a *tonic*; and in alvine hæmorrhages as an *astringent*.

In several diseases it is well known that the blood undergoes alterations in its physical (and in many cases, doubtless, also in its chemical) properties. Thus in some very fatal diseases, (more especially cholera) it seems there is a deficiency of the saline constituents, and it has, therefore, been inferred, that the most efficacious treatment is the employment of saline remedies. But this, however, is not a necessary inference, since, granting that the alteration in the quality of the blood is constant, it must be regarded as an effect of the disease, and not as constituting its essence. During the late severe visitation of cholera in this country, the saline treatment was most extensively tried, and in the opinion of many was very successful, but by others was regarded as useless.

(*b.*) *Injected into the veins.*—Practitioners were not content with exhibiting salines by the stomach in cholera, but injected them into the veins, sometimes to an extent hardly credible. Thus one writer tells us that from 5 to 10 pounds of the saline solution (composed of two drachms of chloride of sodium, two scruples of carbonate of soda, and sixty ounces of water, at the temperature of 108° or 110°), should be injected in an adult, and repeated at larger or shorter intervals, as the state of the pulse and other symptoms may indicate. In one case upwards of 31 pounds were injected in the course of 53 hours. In another case, 30 lbs. were injected in 20 hours!! These injections were had recourse to on the ground that the evacuations upwards and downwards are in reality the serum of the blood; and that we ought as speedily as possible to replace it by injections into the the veins. I must refer you to the 9th and 10th volumes of the MEDICAL GAZETTE for cases in which this practice was adopted.

(*c.*) *Injected into the rectum.*—Salt is an ingredient in the common enema usually composed of one or two table spoonfuls of salt dissolved in a pint of gruel. Sometimes, however, we employ a saline solution to cause the expulsion of worms from the large intestines.

(*d.*) *Externally*, salt has been employed in various cases: thus it is added to water for baths, affusions, &c., to render it more stimulant; as a counter-irritant, a strong solution has been applied to the skin over glandular swellings, &c.

In Germany, a favourite remedy in obstinate cough, hoarseness, and *phthisis laryngea*, is the *testicles of the herring* (*Testes Harengi*), taken in the morning fasting!! Ritter, Neumann, Frank, Siemerling, and Hufeland, have borne testimony to their efficacy, which is said to be owing to the common salt they contain.

CALCIUM.

The compounds of this metal which I shall notice as being medicinal agents are—

1. *Lime*, or the oxide of calcium, and its *carbonate*.
2. *Chloride of calcium*.

1. *Lime*.

History. — Lime (called also *calcareous earth*) has been known from the most ancient times, but the nature of the process for obtaining what is called *quicklime* was first explained by Black, in 1755. In 1808, Davy discovered that lime was composed of oxygen and a metal (*calcium*).

Native state.—It is found in a state of combination both in the organized and inorganized kingdoms.

Preparation.—It is usually obtained by burning the carbonate among coals in a kind of wind furnace, called a *kiln*. In the Pharmacopœia are two formulæ for making it; one consists in heating white marble in a crucible,—the other in heating shells in the same manner. But for pharmaceutical purposes neither of these processes is followed, the common quicklime being usually sufficiently pure for medicinal use.

Properties.—It is a white brittle substance, of an acrid alkaline taste, having a strong alkaline reaction on turmeric and cabbage infusions.

Composition.—Quick-lime, or pure lime, consists of—

1 atom oxygen	8
1 atom calcium	20
1 atom lime	28

Its formula is Ca.

Slacked lime is prepared by pouring water on lime; heat is evolved, the lime falls to powder, part of the water is dissipated in the form of vapour, while the remainder unites with the lime to form *slacked lime* or the *hydrate*, and which is composed of one atom of lime and one of water.

Its formula is Ca H.

Lime water is easily procured by digest-

ing lime in distilled water. It is a curious though not isolated fact, that lime is more soluble in cold than hot water. Thus a pint of boiling water will dissolve only 5·6 grains of lime, whereas the same quantity of water at 32° will dissolve 11·0 grains. The solution is colourless and transparent, but by exposure to the air soon becomes covered with a film of the carbonate, which precipitates to the bottom, and is succeeded by another. By evaporating it under the air-pump receivers, crystals of lime may be obtained. Lime water has an alkaline taste, and reacts as an alkali on vegetable colours.

Characteristic tests.—Carbonates and oxalates precipitate solutions of lime, and of the calcareous salts: a solution of chloride of calcium gives an orange tinge to the flame of alcohol: dilute solutions of lime are not precipitated by sulphuric acid, or the sulphates.

Physiological effects.—Lime is a powerful escharotic and irritant, but less powerful than the caustic alkalies, probably in consequence of its less solubility. When lime water is applied to any of the mucous surfaces, it acts as an astringent, diminishes secretion, and causes dryness of the part; and when swallowed, has a tendency, therefore, to produce constipation. It neutralizes any acid matter it may meet with, and forms therewith a calcareous salt. The action of lime on the system is somewhat different from that of the alkalies, for it is more of a tonic and astringent nature; in consequence of which Vogt ranks this substance between zinc and the alkalies. Furthermore, it is said that the inordinate use of lime does not bring on a scorbutic diathesis, like that of the alkalies.

Uses.—Lime has been employed as a *caustic*, but it is not often resorted to now for this purpose. As an *antacid* lime-water may be employed to neutralize acid which may have been introduced into the stomach from without, or an excessive secretion of acid; however, for the latter purpose the carbonate is to be preferred. As an *astringent* it has been applied to ulcers, attended with an excessive discharge; and in some cases its power in this respect has appeared to me astonishing. In various affections of the alimentary canal, also, it has been employed, on account of its astringent powers; for example, in diarrhœa, especially when the mucous discharge is very great, and the inflammatory symptoms have subsided; so, also, it is used in leucorrhœa, gleet, &c.

As a *tonic* it has been employed in scrofula, dyspepsia, &c. At one time it had great celebrity as a lithontriptic. It constitutes one of the active ingredients in Mrs. Joanna Stephens' "remedy for the stone," the other ingredient being soap, which she gave with the view of keeping the bowels open. As this lady gained great celebrity by her mode of treatment, great interest was felt in endeavouring to discover the medicines she used, and she therefore offered her remedy to parliament. A committee of professional men was appointed to examine the efficacy of her treatment, and the remedy was given to a patient known to have a calculus; he soon got relief, and no stone could afterwards be felt in the bladder. Parliament, therefore, purchased her secret for 5,000*l.*, the grant for which you will find gazetted in June 1739. But, alas for the lithontripic, some time afterwards, the patient died, and on his body being examined, the calculus was found undissolved, but lodged in a pouch communicating with the bladder. Mixed with linseed oil, lime-water forms a kind of soapy mixture, often used with great advantage as an application to burns. Lime constitutes one of the active ingredients in depilatories.

Carbonate of Lime.

History.—Dr. Black was the first to explain the nature of this compound.

Native state.—It occurs in both kingdoms of nature. In the crystallized state it is called *calcareous* spar. In the uncrystallized forms it presents many varieties, of which I may just instance marble, chalk, and marl. It is found in most mineral waters, being held in solution by an excess of carbonic acid. In the animal kingdom it is found in the crustacea, in egg shells, in Russian castor, &c.

Preparation.—In the Pharmacopœia, native chalk is prepared by elutriation—that is, by stirring it up in water, and pouring off the liquid from the heavier particles.

Properties.—It is a soft white substance, too well known to require much description.

Composition.—It consists of

1 atom of carbonic acid	22
1 atom of lime	28
	50

Its formula, therefore, is $Ca\ddot{C}$.

A small portion of hygrometric water is usually present.

Characteristic tests.—Its effervescing with the strong acids readily distinguishes it as a carbonate, while the tests for lime already mentioned will easily indicate the base.

Physiological effects.—It is antacid and absorbent. Taken in very large quantities by a patient affected with pica, Weickardt states that it occasioned total loss of appetite, obstinate constipation (as in lead colic), and emaciation.

Uses.—It is sometimes employed externally as an absorbent, but more frequently internally in diarrhœa.

Administration.—It is usually given suspended in water, as in the *chalk mixture* of the Pharmacopœia.

Sometimes it is used as an adjunct to opium, as in the *compound chalk powder* of the Pharmacopœia. The *aromatic confection* contains chalk, mixed with aromatics.

Chloride of Calcium.

History and synonymes.—This salt, commonly termed *muriate of lime*, was known in the fifteenth century.

Native state.—It is found in sea and many mineral waters.

Preparation.—It is a product in the manufacture of the sesquicarbonate of ammonia; but it may be readily obtained by saturating hydrochloric acid with carbonate of lime.

Properties.—It occurs in regular six-sided prisms, which are very soluble in water. When heated, it melts, and may be deprived of its water.

Composition.—It essentially consists of chlorine and calcium, but in the crystallized state contains water.

	Fused.	Crystallized.
1 atom chlorine,	36	36
1 atom calcium.	20	20
6 atoms water . .	0	54
	56	110

Characteristics.—The tests for this salt are the same as those for hydrochloric acid and lime, already mentioned.

Physiological effects.—In small doses it is said to promote the secretions of mucus, urine, and perspiration, and to have a specific influence over the glandular and lymphatic system, the activity of which it increases. In larger doses it excites vomiting and purging, injures the digestive process, excites the pulse, &c. Hufeland says it is more irritant than the chloride of barium, and that its use requires great caution. In very large doses it causes an affection of the cerebro-spinal system, indicated by trembling of the limbs, convulsions, insensibility, and paralysis, with small pulse, &c.

Uses.—It has been principally employed in scrofula and glandular enlargements; and also in chronic skin diseases, rheumatism, &c.

Doses.—A few grains dissolved in water, gradually increasing the quantity and the frequency of the times of exhibition.

MAGNESIUM.

The compounds of this metal which I have to notice are—the *oxide*, or *magnesia*, and its *carbonate* and *sulphate*.

Magnesia.

History and synonymes.—It was first chemically distinguished from lime in 1755, by Dr. Black, who also shewed the difference between magnesia and its carbonate. It is commonly termed *calcined magnesia*, and sometimes *talc earth.*

Native state.—It is found in both kingdoms of nature: thus the hydrate, carbonate, sulphate, borate, silicate, and nitrate, are found in the mineral kingdom; and the phosphate in animals.

Preparation.—It is obtained by exposing the carbonate to a full red heat in crucibles, so as to drive off the carbonic acid.

Properties.—A fine white light powder, tasteless, but reacting slightly alkaline on vegetable colours (turmeric and cabbage infusion.) It is soluble in water,—more so in cold than hot water.

Composition.—It is composed of—

1 atom oxygen	8
1 atom magnesium	12
1 atom magnesia	20

Its formula is $\dot{M}g$

Characteristic tests.—It is not precipitated by the ferrocyanurets or hydrosulphurets. The monocarbonates of the alkalies (though not the bicarbonates) precipitate it white: from lime it is distinguished by not being precipitated by oxalic acid or the oxalates: it is insoluble in alkalies, and hence is distinguished from alumina. Ammonia with phosphate of soda precipitates the white ammoniacal phosphate of magnesia from solutions of this earth.

The *effects* and *uses* are similar to the sub-carbonate.

Subcarbonate of Magnesia.

History.—This preparation is also called *magnesia alba*, and the *carbonate of magnesia.* It was exposed for sale at Rome at the commencement of the eighteenth century, by Count di Palma (hence the name it received, *Comitissæ Palmæ pulvis*), and, in 1707, Valentini informed the public how it might be prepared.

Native state.—Native carbonate of magnesia constitutes the mineral called *magnesite*,—and is said to compose a range of low hills in Hindostan. The native *hydro-carbonate of magnesia*, a substance very similar to the magnesia alba of the shops, occurs in New Jersey.

Preparation.—Subcarbonate of magnesia is prepared by the action of the alkaline monocarbonates (soda or potash) on the sulphate of magnesia; washing and drying the powder. Sometimes it is made up, while drying, into large square masses

with bevelled edges, or into small cubes. Two kinds of subcarbonate of magnesia are kept in the shops—the light and the heavy.

Light or *flocculent subcarbonate* is prepared by dissolving 8 lbs. of sulphate in 48 lbs. of cold water, and precipitating by 13 lbs. 6 oz. of the monocarbonate of soda, dissolved in twice its weight of cold water, and washing the precipitate with cold water. The compound thus obtained consists of—

Carbonic acid . . .	32	100
Magnesia	33	
Water	35	

Heavy or *gritty subcarbonate* is prepared by dissolving 8 lbs. of the sulphate in 48 lbs. of boiling water, and adding thereto 9 lbs. 6 oz. of the monocarbonate of soda dissolved in 18 lbs. of boiling water, and keeping the mixture boiling for 15 minutes. This compound consists of—

Carbonic acid . . .	35	100
Magnesia	42	
Water	23	

Properties.—The *magnesia alba* of the shops is a white, inodorous, and almost tasteless powder, very slightly soluble in water.

Composition.—It is not a neutral salt, but a mixture (mechanical or chemical) of *carbonate* and *hydrate* of magnesia,—and hence might be termed the *hydro-carbonate*. Now, as the salts from whence it is procured are neutral, it is evident part of the carbonic acid must have escaped. The relative proportions of carbonate and hydrate are liable to variation, and hence, I believe, these two compounds are not chemically combined; but Berzelius entertains a different opinion. Berzelius gives, as the composition of magnesia alba,

Carbonic acid	35·77	or	3 atoms hydrated carbonate of magnesia	153
Magnesia	44·75		1 atom hydrate of magnesia	29
Water......................	19·48			
	100·00			182

And its formula would be—$(\dot{Mg}\,H) + 3\,(\dot{M}\,\ddot{C}\,\dot{H})$

Physiological effects and uses of magnesia and its subcarbonate. — Both preparations neutralize acids,—one without, the other with effervescence. As antacids, they may be employed in poisoning by the mineral acids, or in dyspeptic complaints accompanied by excessive secretion of acid. In the latter cases the pure magnesia is preferable to the carbonate when there is much flatulence.

Magnesia and its subcarbonate diminish the secretion of lithic acid by the kidneys, and on this account are employed in those forms of lithiasis attended with an excessive secretion of this acid or of the lithates. It is probable, therefore, that magnesia becomes absorbed. It has an advantage over the alkalies in these cases, in not being so apt to produce disorder of the digestive organs.

Magnesia and its subcarbonate promote secretion from the alimentary membrane, and in large doses act as laxatives. For this purpose it is employed as a mild purgative for children; in affections of the rectum (as stricture and piles), in diarrhœa, &c. The objection to the repeated and continued use of magnesia is, that it sometimes accumulates to a large extent. In one case recorded, a mass of from four to six pounds was found in the colon six months after the patient had ceased to employ any magnesia.

Administration. — We employ either of these preparations in doses of from a scruple to half a drachm.

Sulphate of Magnesia.

History and synonymes.—This salt, discovered by Grew in 1694, has been known by various names, such as *Epsom* or *bitter salt*, *Sal Anglicum, Sal catharticum, Vitriolated magnesia*, &c.

Native state.—It is met with in sea-water, and many mineral waters; it occurs as an efflorescence in other minerals, and is found in the mineral called *reissite.*

Preparation.—At one time it was prepared from the Epsom waters, then from *bittern* (the liquid left after common salt is deposited from sea-water.) In Italy it is prepared by roasting schistose minerals containing sulphur and magnesia, by which process the sulphur is converted into sulphuric acid.

Magnesian limestone (a mineral composed of carbonate of magnesia and carbonate of lime) is the substance from which Epsom salts are now manufactured in this country. It occurs in large quantity in several counties. The mineral being calcined, and thereby deprived of its carbonic acid, is mixed with just as much pyroligneous acid as will saturate the lime,—by which means acetate of lime is procured in solution, while the magnesia is left free. The latter is then converted into the sulphate either by adding sulphuric acid or the sulphate of iron: if the latter be employed, the oxide of iron is precipitated.

Properties. — The primary form of the crystals of this salt is a right rhombic prism. Their taste is cooling and bitter.

At 55°, 100 parts of water dissolve 90 of the crystallized salt.

Composition.—The crystals consist of

1 atom sulphuric acid ..	40
1 atom magnesia	20
7 atoms water..........	63
	123

The formula, therefore, is $\dot{\text{M}}\text{g}\ \dddot{\text{S}}\ 7\ \dot{\text{H}}$.

Physiological effects and uses.—It acts as a mild purgative, increasing the secretion as well as the peristaltic motion of the alimentary canal. It is commonly regarded as a cooling or antiphlogistic purgative, and, therefore, well adapted for febrile and inflammatory cases. It is quite analogous to the sulphate of soda, both in its effects and uses. It is rarely given alone, but generally with more stimulating purgatives, such as senna. Its usual dose is from 2 to 8 drachms.

ALUMINUM.

The only compound of this metal employed in medicine is the double salt, commonly termed alum.

Aluminous Sulphate of Potash, or Alum.

History and synonymes.—Although the term alum occurs in the writings of Herodotus and others, it is not quite satisfactorily ascertained that it referred to the salt now bearing this name. On the contrary, the learned Beckmann thinks it alluded to sulphate of iron, and that our alum was discovered in the East, in the 12th century. I must refer those curious in these matters to his *History of Inventions*, and to Parkes' *Chemical Essays*, for further information on this subject. The synonymes for this salt are, *sulphas aluminæ et potassæ*, and *potash sulphate of alumina*. The latter term, though adopted by Dr. T. Thomson, of Glasgow, seems to be objectionable, since it is clear the sulphate of potash, and not the sulphate of alumina, is the basic body.

Native state.—It is found native in the neighbourhood of volcanoes, under the name of *native alum*, *alum stone*, *&c.*

Preparation.—The method of preparing alum is not the same in all places. Thus the process at Whitby is different to that at Paisley. *Alum slate*, or *schistus aluminaries*, contains sulphuret of iron, alumina, and a bituminous substance. By roasting, the sulphur is oxidized and converted into sulphuric acid, which, with the alumina, forms sulphate of alumina: this is converted into alum by the addition of a salt of potash.

Properties.—This salt usually crystallizes in octahedrons. Its taste is acid and astringent, but also somewhat sweetish. When heated, it melts in its own water of crystallization, loses 44 per cent. of water, and forms *burnt alum*. It is soluble in three-fourths of its weight of water.

Composition.—In consequence of the uncertainty of the atomic weight of alumina, chemists are not agreed as to the atomic constitution of this salt.

	Thomson.		*Berzelius.*	
Sulphate potash ..	1 atom =	88	1 atom =	88
Sulphate alumina ..	3 atoms =	174	1 atom =	174
Water	25 atoms =	225	24 atoms =	216
		487		478

Physiological effects.—The local effects of alum are those of a powerful astringent. Applied in small quantities to the gastro-intestinal membrane, or in the form of a dilute solution, it diminishes secretion and exhalation, and thereby causes dryness of the part. In large doses it strongly contracts the stomach, occasions vomiting, and even purging, and acts as a local irritant. In some persons alum causes constipation. The salt is supposed to become absorbed, and to act as a tonic on remote parts of the body.

Uses.—We employ alum to diminish discharges from the mucous membranes: thus solutions of it are injected in leucorrhœa and gleet, or applied to the eye in purulent ophthalmia, especially of children, and taken internally in chronic diarrhœa. Applied to wounds, it is used as a styptic; and for the same purpose it is employed in internal hæmorrhages of an atonic character. To produce contraction or corrugation of parts it is sometimes used; for example, in relaxed uvula, or sore throat. It has been employed also in intermittents.

Administration.—Internally it may be given in doses of from gr. x. to half a drachm. In the Pharmacopœia there is a *compound solution of alum*, containing alum and sulphate of zinc.

In letting of blood three main circumstances are to be considered,—*quis*, *quantum*, *quando*: and, as Aretæus saith, *before you let blood, deliberate of it.*—Burton.

ON THE

POISONOUS PROPERTIES OF HEMLOCK,

AND ITS ALKALOID CONIA *.

By Robt. Christison, M.D. F.R.S.E.

Professor of Materia Medica in the University of Edinburgh.

Few poisons are of greater interest, in a historical or scientific point of view, than hemlock. It has been known ever since the most classic periods of antiquity, being generally believed to have been the κωνειον of Nicander and Theophrastus, and commonly thought to have been the poison with which state-criminals were despatched in ancient Athens. Since that period it has occupied a prominent place in all works on Toxicology; and it has been immemorially familiar as a deadly poison to the vulgar in every part of Europe, where there is scarcely a country or even a province which does not produce it in abundance. For nearly a century, too, since the writings of Baron Storck, of Vienna, in 1762, it has been constantly in the hands of the physician as a remedy, and has been currently employed at different times in the treatment of some of the most common, as well as in some of the most malignant, of all the maladies to which the human body is liable.

To its importance, as thus indicated, the attention which it has received from scientific men, and more especially from the chemist and the physiologist, has been by no means commensurate. There is scarcely a chemical analysis of hemlock worth mentioning, till Giseke, in 1827, succeeded in concentrating its active properties in a compound with sulphuric acid, of such energy, that two grains killed a small animal in fifty-five minutes†; and it was not till 1831 that its active principle was detected and detached by Professor Geiger, of Heidelberg, and proved by him to be one of a new order of organic alkaloids,—not fixed and crystalline like those previously known, such as morphia, strychnia, cinchonia, and the like, but volatile and oleaginous in their physical form ‡. Prior to this discovery, the knowledge possessed of the physiological effects of hemlock was vague and meagre; and little has since been done to supply the defect. The ideas entertained by the Greek and Roman naturalists and physicians of the poisonous properties of the ancient κωνειον or *cicuta*, were for the most part contradictory or obscure. Their statements, however, were long adopted by modern physiologists without examination, and applied to the *Conium maculatum*, or spotted hemlock of botanists; and the small amount of original inquiry which has been attempted by late experimentalists has added little to the previous stock of knowledge. It is surprising, however, that some late researches were not carried farther than they have been; for it would appear scarcely possible for any accurate observer to attend carefully to the phenomena produced by hemlock and its alkaloid in their action on the animal body, without remarking that they are in many respects among the most interesting and extraordinary of all poisons.

These views, and the physiological facts to be subsequently related, were brought under my notice during an attempt made last autumn to repeat the analytic researches of Professor Geiger. As these researches are too little known in this country, or indeed out of Germany, and I have had occasion to confirm almost every fact advanced by the Heidelberg professor, I have thought it not inopportune to reproduce here the general heads of his analysis, as introductory to the principal object of this paper,—which is, "The Poisonous Properties of Hemlock, and its Alkaloid Conia."

A short time before the analysis of Professor Geiger, it was observed by Giseke, that, on distilling hemlock with water and caustic lime, an alkaline liquid, of a strong and peculiar odour, was obtained; from which, when neutralized by sulphuric acid and concentrated by evaporation, he separated with alcohol a substance of the nature of an extract, possessing the poisonous properties of hemlock in a very eminent degree. Two grains of it killed a rabbit in less than an hour. But Giseke was unable to detach either an alkaloidal or a crystalline principle.

Proceeding in the same line of investigation, but with more precision, Geiger first found that the distilled water of hemlock leaves, or of the green seeds, although it gives out very strongly the peculiar mousy odour of the plant, is scarcely if at all poisonous;—a remarkable fact, when we consider that this odour or aroma is usually thought to be a correct measure of the relative activity of different specimens, and to possess a narcotic or stupifying tendency on those exposed to it. The imagination has probably had much to do in the formation of these notions. At all events, we now know that the singular aroma of hemlock is owing, like other

vegetable odours, to a volatile oil; and that this oil is very feebly if at all deleterious.

But if the green seeds or leaves, either after or before the separation of the volatile oil, be distilled with water and caustic potass or lime,—the heat being applied through means of a muriate of lime bath, to prevent charring,—it will be found that the liquid which passes over is strongly alkaline and highly poisonous; and I have also commonly observed, where ten or twelve pounds of seeds were worked in one operation, that an oily-like matter comes over with the first few ounces of liquid, which is soluble in acids, insoluble in alkalies, strongly alkaline in its action on turmeric, and of a powerful, peculiar, suffocating odour, allied to, yet by no means identical with, that of the fresh herb. This, in fact, is a small quantity of tolerably pure conia.

But the greater part of the alkaloid remains in solution in the water which is distilled over. If this distilled water be distilled anew, it is simply reproduced without any material change except some loss of strength. But if it be previously neutralized with an acid, such as the sulphuric, the volatile poisonous principle becomes fixed, and water alone is distilled over. The residuum consists of sulphate of conia, sulphate of ammonia, and resinoid matter, the resin and ammonia being produced by decomposition of a part of the conia under the operation of heat and the access of air. In order to obtain the conia, the mass is subjected to a mixture of two parts of rectified spirit and one of sulphuric ether, which leaves the sulphate of ammonia undissolved. And then, the ether and alcohol being distilled carefully off, the remaining sulphate of conia is heated gently with a little water and caustic potassa; upon which there is obtained in the receiver a watery solution of conia in the lower part, and floating on this a layer of nearly pure conia, colourless, transparent, and presenting the physical appearance of an oil.

In this state the conia contains a little ammonia and a fourth of its weight of water, the latter of which may be removed by chloride of calcium, and the former by exposing it to the air-pump vacuum so long as bubbles of gas escape. By neither process of purification, however, is the physical appearance of the conia materially changed.

Conia thus obtained has the appearance of a colourless volatile oil. It is lighter than water, of a very powerful diffusible repulsive odour, somewhat like that of hemlock itself, and intensely acrid to the taste. It has a strong alkaline action on reddened litmus or turmeric. It is readily soluble in diluted acids, which it neutralizes; but its salts have not yet been obtained in the crystalline form. It is sparingly soluble in water, to which it imparts its odour and taste. It also combines with about a fourth of its weight of water to form a hydrate of conia. Both this hydrate and the watery solution possess the property of becoming opaque when slightly heated, and recovering their transparency on being again cooled. When exposed to the air it quickly contracts a dark brown colour, and is slowly resolved into a resinous matter, with the disengagement of ammonia. This change takes place more promptly under the co-operation of heat; but even at common temperatures it is so apt to ensue, that unless the alkaloid be kept very carefully excluded from the air, discolouration will be accomplished in a few hours. When heated with water it readily distils over at the temperature of 212°, in the same manner as the volatile oils; but its boiling point is 370° Fahr. It cannot be distilled either alone or with water, without a considerable part being decomposed and converted into a resin. Like other vegetable alkaloids, it is an azotized principle; and, according to an analysis by Liebig, it is composed of—carbon 66·91, hydrogen 12·0, oxygen 8·28, and azote 12·8*.

By the process mentioned above, conia may be obtained from the leaves of hemlock collected immediately before or during inflorescence of the plant. It exists, however, in much larger proportion in the seeds when fully developed, but still green. Even in them the quantity is small: from forty pounds I obtained about $2\frac{1}{2}$ ounces of hydrated conia. Geiger states that he obtained a still larger proportion from the ripe seeds; a result, however, which has not been confirmed in the trials I have made. It is very probable that a much larger proportion exists in both the leaves and seeds than has yet been obtained. For at every stage of the process where heat is applied, however carefully the heat may be managed, it is evident, from the abundant formation of ammonia, that much of the alkaloid is decomposed.

An important fact observed by Geiger is, that the dried leaves of hemlock and some extracts of their juice do not contain any conia. This observation I have also had occasion to make in regard to various extracts. It is interesting, in relation to the well known circumstance that the greatest discrepancy prevails among medical men as to the activity of hemlock, not merely as a remedy but even also as a poison. Two drachms of extract have been given to a dog without marked effect

* Magazin für Pharmacie, xxxvi. 161.

of any kind, and even an ounce has acted only as a feeble poison*; while it will presently be found that the same preparation is sometimes a poison of exceeding energy.

These discrepancies are easily understood now, on considering the extreme proneness of conia to decomposition, provided the conia of Geiger be the true active principle of hemlock. From what has come under my observation, the extracts of hemlock may become feeble, if not even inert, in one of two ways,—either by the heat being continued after the concentration has been carried on to a certain extent, or by long keeping. On the one hand, I have always observed, that from the point at which the extract attains the consistence of thin syrup, ammonia begins to be given off in abundance, together with the modified odour of conia. And on the other hand, I have found extracts which were unquestionably well prepared at first, entirely destitute of conia in the course of a few years,—a remark which applies even to the superior extract prepared by Mr. Barry, of London, by evaporation *in vacuo*. The mode of ascertaining the presence of conia is simply to triturate the extract or other preparation with solution of potassa, upon which an odour of conia is given off. I have no doubt that potassa is in this way a test of very great delicacy.

Of the various extracts I have examined, that which has yielded the largest proportion of conia is one prepared by alcohol from the ripe seeds. Two hundred and twenty grains gave towards five grains of colourless hydrate of conia. From this preparation, indeed, it is probably to be obtained with more ease than from any other. I have prepared it quite colourless and free of all impurity but water, by exhausting ground hemlock-seeds with cold rectified spirit in a perculator; distilling off the spirit and concentrating in an open vessel over the vapour-bath till the residue had the consistence of syrup, and subjecting this extract, in a proper distilling apparatus, with its own weight of water and a little caustic potassa, to the heat of a concentrated boiling solution of muriate of lime. The conia passes over readily with the water, floating on its surface and quite colourless.

In the proximate analysis of organic substances, it is of primary consequence that the agents employed be such as will accomplish simple separation of the proximate principles from each other, without producing new compounds by a new arrangement of elements. Some chemists have entertained doubts whether even any of the methods of analysis at present in use fulfil correctly this condition. But all are agreed in thinking that the agency of strong acids or strong alkaline solutions, more especially when concurring with an elevated temperature, should in general be avoided, as tending rather to form new compounds than simply to detach compounds already formed by nature. Hence a question may justly arise, whether the substance I have been describing is the real active principle of hemlock, or a new product formed by the action of caustic potassa aided by heat?

Here it may be observed, in the first instance, that heat is not necessary for the development of conia in hemlock and its preparations; for its peculiar odour is at once disengaged from the powder of the seeds when treated with solution of potassa at ordinary atmospheric temperatures.

By far the most direct and satisfactory test, however, of the force of the above objection in such circumstances, is the effect of the detached principle on the animal body, and the relation the phenomena bear to those produced by the crude substance from which the principle is obtained. In the present case, experiment amply proves that the conia of Geiger concentrates in itself the properties of hemlock,—and, if not itself the true active principle, must contain it in large quantity.

The researches of Geiger on this head are few in number, and were chiefly confined to small birds as the subject of experiment. Nor does he seem to me to have correctly interpreted the phenomena, since he describes the animals as having been affected with paralysis and tetanic convulsions, and as presenting, immediately after death, congestion and loss of irritability of the heart, with unimpaired irritability of the voluntary muscles, the diaphragm, and the intestinal canal. The natural inference would be that conia proves fatal by paralyzing the heart.

On making trial of its effects on one of the higher orders of animals, I obtained results so different and so remarkable, that I was led to investigate its physiological action in detail. The facts thus brought under my notice will shew that this substance is one of the most extraordinary of all known poisons, looking either to its uncommon energy and subtilty, or to the peculiar phenomena and nature of its operation. In what follows I shall confine myself to a general summary, reserving the details of special experiments for an appendix.

I should premise that the anatomical details were conducted by Dr. Sharpey, and the whole experiments made in the presence of various practised observers.

* Orfila, Toxicologie générale, ii. 305.

This it is material to state, because in physiological inquiries like the present, where the incidents succeed one another with extreme swiftness, it is indispensable that the anatomical part be executed with facility, certainty, and despatch, and that the account taken of what passes be checked by several competent observers.

Conia is probably a deadly poison to every order of animals. It acts, at least, with great, and apparently equal energy, on the dog, cat, rabbit, mouse, kite*, pigeon*, sparrow*, frog, slow-worm*, earthworm*, fly, and flea.

It acts through every texture of the body where absorption is carried on readily—namely, when put into the stomach, or dropped into the eye, or inhaled into the lungs, or introduced into the cellular tissue under the skin, or brought in contact with the peritoneum, or injected directly into the veins. Its activity through these several channels seems on the whole proportional to the speed with which absorption is carried on by each texture; so that it is one of the poisons which act through absorption. Nevertheless, a fact will be mentioned by and by, which would indicate that something more than absorption into the blood is required before it can affect those vital functions, whose arrestment constitutes the cause of death, and the essence of its operation.

The activity of conia is not impaired, but rather the reverse, by neutralization with an acid. Geiger arrived at a different conclusion, for he says "its poisonous effect is greatly lessened by union with acids." Such a fact would be at variance with a law in physiology hitherto found to be universal; that poisons acting through absorption are not at all, or very little, altered in their effects by any change in chemical form, provided they continue equally soluble. As the salts of conia are more soluble than the alkaloid itself, we should expect them to act with at least equal energy. And, accordingly, I have always found that the activity of a poisonous dose was materially increased by using it neutralized with muriatic acid. It will follow as a corollary, that the discovery of a chemical antidote for conia or hemlock is extremely improbable.

The chief features in the action of conia are the following:—It is, in the first place, a local irritant; it has an acrid taste; when dropped into the eye, or on the peritoneum, it causes redness or vascularity; and to whatever texture or part it is applied, expressions of pain are immediately excited. But these local effects are soon overwhelmed by the indirect or remote action which speedily follows. This consists essentially of swiftly spreading palsy of the muscles,—affecting first those of voluntary motion, then the respiratory muscles of the chest and abdomen; lastly the diaphragm, and thus ending in death by asphyxia. The paralytic state is usually interrupted from time to time by slight convulsive twitches of the limbs and trunk in the early stage of the poisoning; but this is not an essential phenomenon. The muscular contractility of parts directly acted on,—as when a voluntary muscle, a loop of intestine, or the heart, is brushed over with conia or its muriate,—is sometimes impaired, sometimes almost immediately annihilated. But this effect, as will be evident from the details of the experiments, is not invariable. Under the remote or indirect action of the poison, the muscular contractility remains altogether unaffected: when an animal is killed with the poison applied to the eye, a wound, or the like, both the voluntary and involuntary muscles contract for a long time after death, when stimulated, either directly or through the medium of their nerves, by mechanical irritation, or by galvanism. The blood undergoes no apparent alteration, except those incidental to death by asphyxia; it coagulates firmly after death, if immediately withdrawn from the blood-vessels. The heart, contrary to Geiger's statement, remains wholly unaffected,—contracting vigorously for a long time after all motion and respiration, and other signs of life, are extinct,—and containing after death not florid, but dark blood in its left cavities. The external senses continue little, if at all, impaired, till the breathing is nearly arrested; and volition is also retained. The action of conia, in short, is exerted chiefly on the spinal cord. In its nature that action is the counterpart of the action of nux vomica, and its alkaloid strychnia. Strychnia irritates the spinal cord, producing violent permanent spasm of the muscles, and death by asphyxia from spasmodic fixing of the chest. Conia, on the contrary, exhausts the nervous energy of the spinal cord, producing general muscular paralysis, and asphyxia from relaxation.

Few poisons equal conia in subtilty or swiftness. A single drop put into the eye of a rabbit killed it in nine minutes; three drops used in the same way killed a strong cat in a minute and a half; five drops poured into the throat of a small dog began to act in thirty seconds, and in as many seconds more motion and respiration had entirely ceased. But the most extraordinary evidence of its power is obtained by injecting it into a vein. Magendie, speaking of the concentrated or pure prussic acid when similarly applied, compares its action to that of a cannon

---

* Animals experimented on by Geiger.

ball or thunderbolt: "La foudre n'est pas plus prompte." Figurative as this language may be, it is the only mode of conveying an adequate idea of the effect of conia when injected into the blood. Proceeding to inject into the femoral vein of a young dog two grains of the alkaloid, exactly neutralized with thirty drops of diluted muriatic acid, I was prepared for great rapidity of action, and was going on the instant to observe the time by seconds; but on glancing for a moment over the watch at the animal, I observed it was dead. In two seconds, or three at farthest, and without the slightest warning struggle, respiration had ceased, and with it all external signs of life.

Of the effects previously related, some are most clearly seen where the progress of the poisoning is slow, others where the action is rapid. It is only, for example, where death takes place rather slowly, that we can satisfy ourselves of the maintenance of the functions of the external senses; because in other circumstances the instant invasion of paralysis of the voluntary muscles takes away all power of expression, by which alone we can judge of the state of the senses. But when the poison is given so as to operate slowly, then distinct evidence may be obtained that both sight, touch, and hearing, are retained so long as the most feeble power of movement is preserved, so that sensation may be followed by expression. The integrity of the circulation and muscular contractility, is, on the other hand, best shewn where death is prompt. When the poison acts slowly, the heart after death is found gorged, and contracting feebly or imperfectly;—a physiological phenomenon not connected with any peculiar action of the poison on the heart, but which is common to all modes of death by slowly-formed asphyxia. But where the action is swift, and asphyxia prompt and complete, the heart acts spontaneously with great force even in the higher order of animals for a great length of time. I have seen spontaneous contraction of the ventricles of the heart go on ten minutes, twenty minutes, nay, even thirty minutes, after death, in the rabbit; and have witnessed unequivocal contraction of the auricles when scratched even so late as after an interval of sixty minutes. The most striking illustration, however, of the integrity of the heart is obtained by keeping up respiration artificially when it has ceased: after the breathing had almost ceased in seventeen minutes in a dog poisoned with six drops through a wound, and when two minutes more would undoubtedly have put an end to life, artificial inflation of the lungs was commenced, and continued with occasional intervals for thirty-five minutes. During all that time the heart beat with its natural force, except when the inflation of the lungs was suspended;—the animal remaining all the while in a state of paralytic flaccidity, interrupted only by slight muscular twitches. It appears probable that there is scarcely any limit to the maintenance of the circulation under artificial breathing, except what may arise from the difficulty of imitating exactly the natural respiration, as well as from the several causes which occasion cooling of the body. There is little doubt, therefore, that where the dose of the poison is not very great, animation may be restored by maintaining the function of respiration artificially till the deleterious agent or its effects be thrown off,—just as in some other forms of narcotic poisoning. And when we consider the whole physiological phenomena, it will appear that this is the only treatment which promises material success.

There are several other physiological facts relative to the action of this poison, which are not devoid of interest, but which it would be tedious to dwell on here. They will be best examined by consulting the appendix of experiments. This department of my subject, therefore, may now be concluded with a few remarks on the question, through what channel the action of conia on the spinal cord is accomplished: does it act by being carried substantively with the blood to that organ, or by the transmission along the nerves of a peculiar impression made on the texture where it is directly applied? I must leave the question, however, in an unsettled state. Every physiologist who has attended to the late researches in this field, must agree that we are not at present in possession of any accurate criterion for settling the question in the case of any poison which acts remotely, that is, on organs at a distance from the part where it is immediately applied. That absorption is somehow connected with the action of conia, will appear from its activity seeming proportional to the activity of absorption in the texture with which it comes in contact. This inference would be strengthened if we could actually detect it in the blood after death; but my observations on this head are contradictory; for, in one instance, where the muriate of conia was put into the stomach, and secured there by a ligature on the gullet, its odour was distinctly remarked after death in the general cavity of the abdomen; while in another case, where death followed in ninety seconds the application of conia to the eye, not the slightest odour could be detected in the blood of the heart. It would seem to me, however, to be very nearly made out by a fact already men-

tioned, that, although absorption into the blood may be a part of the chain of consequences which attend the action of conia, yet this is not all; and that the poison does not act by being carried substantively with the blood to the spinal cord. I allude to its tremendous rapidity when injected into a vein. That it acts more sw ftly in this way than in any other, is evidence enough perhaps that it enters the blood before it operates. But farther, its effect, when thus introduced, is too swift for its action to depend entirely on the blood becoming poisoned, and itself acting on the spine; for it is impossible that, in three seconds, which was certainly the limit of interval when all voluntary movement and respiration had ceased, the poison could have passed with the blood from the femoral vein to the heart, from the heart to the extreme ramifications of the pulmonary artery, back again to the heart by the pulmonary veins, and, lastly, by the general arterial system to the spine. If a correct view of the facts be here taken, there scarcely seems any refuge for the physiologist, except in the doctrine, that conia acts by entering the blood, and producing on the inner membrane of the blood-vessels a peculiar nervous impression, which is instantly conveyed by sympathy along the nerves to the organ remotely and ultimately affected.

After these remarks on the properties of conia, it remains to be seen whether they coincide with what is known of the properties of hemlock itself. On this question hangs the ulterior one, whether conia is the true active principle of the plant.

[To be continued.]

Physiological Reflections.

Are the properties of the animal fluids, indicated above, only interesting to the chemist, or are they not also interesting to the physiologist, as serving to explain some of the phenomena of the living body? I shall state my reasons for believing that these properties are intimately connected with the functions of the lymphatic system, and in that way constitute an essential element in the process of sanguification. I shall thereafter mention some other physiological and pathological phenomena, which appear to me to admit of elucidation on similar principles.

Functions of the lymphatic system.—The remarks I have to offer on the functions of the lymphatic system, and the process of sanguification, I commence by inquiring—What is the use of the serous fluid exhaled into the great cavities and cellular substance of the body? The doctrine taught by Magendie, and at present generally received in the schools of medicine, is that the serous exhalations and the fat are chiefly useful in the human body from their physical qualities. The serum of the great cavities is said to lubricate the viscera, and enable them to move easily upon each other; while the serum of the cellular substance performs the same function with respect to the cellular substance itself, and the muscular fibres and other organs between which it is interposed. The fat, again, is regarded as a kind of stuffing, intended to fill up the vacuities, and round off the asperities and inequalities in the structure of the body. Now, while I think that it cannot be disputed that the serum and fat answer the ends thus ascribed to them, I also think that it is to take a very narrow view of the utility of these secretions to conceive that they answer no more important ends in the animal economy. The observation of Pope will, I believe, be found to apply here, as in most other instances, to the works of nature as contrasted with those of man, to the level of which our interpretations of the former too often tend to degrade them:—

> In human works, though laboured on with pain,
> A thousand movements scarce one purpose gain:
> In God's, one single can its end produce;
> Yet serves to second, too, some other use.

The serum poured out by the exhalent vessels does not remain in the cavities and cells into which it is effused, but, being re-absorbed, is carried back into the circulation. When we consider the extent of the great serous cavities, and the universal diffusion of the cellular

membrane over the body, it must be obvious that the quantity of liquid passing through the never-ceasing processes of exhalation and re-absorption must be very great. We conclude, then, that a very large quantity of membranous serum is elaborated in the great cavities and cellular substance, and thereafter carried back into the circulation. By what route, and for what purposes, is it so carried back? There are only two known routes by which it can be carried back—through the veins, or through the lymphatics—and by which ever route it is carried back, it must modify the constitution of the mass of circulating blood; for on being mingled with the sanguineous serum, it will exert the same re-action within the body, which it has been shown above to exert on sanguineous serum out of the body. There are, however, many reasons which lead me to believe that the serum of the membranes is absorbed by the lymphatic vessels. There are also certain reasons which lead to the belief that a portion of the serum of the blood returns to the general circulation by the same route. Should the arguments urged in behalf of these opinions appear satisfactory, it will follow that the membranous and sanguineous serum which enter at the extremities of the lymphatic system, must be mingled together in the lymphatic vessels and glands, and must consequently be modified in their qualities; and in corroboration of that conclusion, it will be found that the liquid, which, after passing through the lymphatic vessels and glands, reaches the thoracic duct, differs in qualities both from the serum of the membranes and the serum of the blood, inasmuch as it possesses the property of spontaneous coagulability; a property which neither species of serum possesses separately, but which belongs to a mixture of the two.

The physiological doctrine stated above depends upon the three following fundamental propositions. 1st. That the lymphatic vessels absorb the membranous serum of the great cavities and cellular membrane. 2d. That there is a communication between the arteries and lymphatics, by which a portion of the serum of the blood passes from the former into the latter system of vessels. 3d. That the membranous and the sanguineous serum introduced into the lymphatic system are thoroughly mingled in the lymphatic vessels and glands, and form together a fluid possessing spontaneous coagulability, and constituting the basis of the clot or crassamentum of the blood. On each of these propositions I shall offer a few remarks.

1st. It is only of late years that any evidence would have been required for the first of these propositions, that the lymphatic vessels absorb the membranous serum from the great cavities and cellular membrane. The lymphatic vessels were universally believed, according to the doctrine of Hunter and Cruikshank, to absorb both the membranous serum, and every other absorbable substance, whether generated within the body or introduced from without.

Now, however, the experiments of Magendie, and the labours of Tiedemann and Gmelin, have restored the ancient doctrine of venous absorption. It has been certainly established that the veins are capable of absorbing, and there is every reason to believe that they do actually perform some of the most important parts of the absorbent function in the animal body. It appears to me, however, that in ascribing all absorption to the veins, and divesting the lymphatic vessels altogether of the absorbent faculty, the advocates of this new doctrine have carried it further than is warranted, either by experiment, or by sound reasoning. Substances injected into the cavities of the peritoneum it was found could not be discovered in the fluid of the thoracic duct by their colour, by their smell, or by the assistance of chemical re-agents. From the experiments the only fair inference is, that the substances in question are not absorbed by the lymphatics, but no conclusion can be more unwarrantable than that which Magendie has drawn, that the lymphatic vessels are altogether destitute of the absorbent faculty. For, although incapable of absorbing such foreign substances, the lymphatic vessels may still be capable of absorbing the peculiar fluid which they are always found to contain, and to absorb which may be their special function in the animal economy. This reasoning will appear in a clearer light by applying it also to the lacteal vessels, of which the absorbent function is incontestible. Magendie introduced into the stomach and bowels substances similar to those which he introduced into the cavity of the peritoneum, and

capable of being recognized by their colour, by their odour, or by their chemical qualities; and he never could detect any of those substances in the thoracic duct. He infers justly that the lacteals are incapable of absorbing such substances; but if he were to reason as he does with respect to the lymphatics, he would also infer that the lacteals do not absorb at all. The only legitimate conclusion which can be made from the experiments of Magendie with respect both to the lacteals and to the lymphatics, is, that neither set of vessels is capable of absorbing the substances foreign to the animal economy with which he experimented, but it is most illogical to infer that these vessels are destitute of the absorbent faculty. One of them is certainly known to possess, in the most eminent degree, the power of absorbing; and the complete analogy which, in every point of view, exists between these two sets of vessels, would lead us to infer that the same power is possessed also by the other. Still further, while the lacteal vessels are found to reject all other substances submitted to their action, it is known assuredly that there is a peculiar fluid which they suck up with avidity, being, as it would appear, the only fluid which it is the province of these vessels to introduce into the system. Reasoning, therefore, again from analogy, we may infer with respect to the lymphatic vessels, that while they are found by experiment to reject all other substances submitted to their action, there may be a peculiar fluid which they readily absorb, and which it is their special province to carry into the general circulation. This view of the subject, suggested by analogy, is confirmed by other arguments. It is, indeed, much less easy to establish the existence of a peculiar circulating fluid, with respect to the lymphatics, than it is with respect to the lacteals. In the lacteals the circulating fluid is opaque and white, the most superficial inspection is sufficient to establish the existence, and its origin is equally evident from the chyme formed in the alimentary canal during the process of digestion. In the lymphatics, on the contrary, the circulating fluid is transparent and colourless, or at least has, for the most part, very little colour. It is, therefore, so little conspicuous, that it can only be discovered on the most minute inspection. In spite of these difficulties, however, it is now certainly known that the lymphatic vessels do contain a peculiar fluid, to which we give the name of lymph: and moreover, it has been ascertained that this fluid is uniform in its character, in whatever part of the body it has been examined, shewing clearly that it must proceed everywhere from the same common source. Now, it is certain this fluid does not proceed from without, and it must, therefore, have its source in some of the animal fluids in contact with the extreme branches of the lymphatic system. The animal fluids, which are diffused all over the body wherever lymphatic radicles exist, and which most closely resemble the lymph in appearance, are the membranous serum of the great cavities and cellular membrane, and the serum of the blood. So closely does the lymph resemble these fluids in its qualities, that, while most physiologists have regarded it as identical with the menbranous serum, Magendie, and some of the earlier writers upon the lymphatic system, look upon it as the same with the serum of the blood, and Haller considers the whole three fluids as identical. There is, however, one property in which the lymph differs both from the membranous serum and from the serum of blood. The lymph posssesses the property of spontaneous coagulability. Now neither the membranous serum nor the serum of the blood coagulate spontaneously, but a mixture of these two fluids, while it exactly resembles the lymph in all its other qualities, possesses also the property of spontaneous coagulability. So far, therefore, as a judgment can be formed by comparing the qualities of the lymph with the qualities of the animal fluids in which it may possibly originate, it seems most probable that the fluid which circulates in the lymphatic vessels is a mixture of membranous and sanguineous serum. This conclusion will be much corroborated if the second proposition, stated above, can be established as correct. We proceed, therefore, to examine that proposition.

2d. The second proposition is, that there is a communication between the arteries and the lymphatics, and that a portion of the serum of the blood passes from the former into the latter system of vessels. The first part of this proposition—that there is a communication between the arteries and the lymphatics—

may be explained by supposing these two systems of vessels to be continuous with each other, in the same way as the arteries and veins; or, in other words, that there is a direct inosculation between the capillary arteries and the extreme vessels of the lymphatic system. It is a fact admitted by all the earlier writers upon the lymphatic system, and since confirmed by Haller, Meckel, Magendie, and many other distinguished anatomists, that penetrating injections thrown into the arteries return by the lymphatics. The same result is obtained when an injection is thrown into the veins or the excretory ducts of the liver, the kidney, or the testis. These facts seem to establish a free inosculation of the roots of these four orders of vessels—the arteries, the veins, the lymphatics, and certain excretory ducts; or perhaps, to speak more correctly, that these four kinds of vessels originate in the same capillary net-work, which Bichat has elevated to the rank of a distinct system of vessels, under the name of the capillary system.

Two other suppositions have been made, to explain the communication between the arteries and lymphatics: the one, that these vessels only communicate indirectly, the fluids being first effused into the surrounding tissues, and being then taken up by the lymphatics; the other, which is that of Mascagni, that the communication may be effected by means of lymphatic vessels, of which the mouths open on the internal surface of the arteries. I would remark, however, with respect to these two latter suppositions, that whatsoever explanation they may afford of the transition from the arteries to the lymphatics, of the fluids naturally circulating in these vessels, or even of the injections thrown by Magendie into the arteries of live animals, they cannot explain the passage of injections in animals some time dead; for in them the absorbing power of the lymphatic vessels is gone, and we cannot, therefore, expect to fill those vessels with our injections, any more than we can expect to fill the lacteals by injecting the small bowels. These opinions, therefore, appear to me hypothetical, and much less probable than the opinion first stated—that there is a direct communication, by inosculation, between the extremities of the arteries and those of the lymphatic vessels.

By examining the fluid contained in the lymphatic vessels, it is ascertained that the coagulable part of the blood does not pass from the arteries into the lymphatics, but only the serum, or the serum tinged with a certain quantity of colouring matter. It would appear from the experiments of Magendie, that the quantity of colouring matter varies according to circumstances. When animals are kept without food for several days, the red colour of the lymph becomes more and more deep with the duration of the abstinence.

Before proceeding to examine the third proposition, I would remark, that the origin which I have ascribed to the lymphatic vessels is by no means new, although it may appear so to those who have been trained in the exclusive doctrine, that the lymphatic vessels are the only absorbents, and that they have no other function than to absorb. But before the promulgation of this exclusive doctrine, the opinion generally entertained was, that the lymphatic vessels had the origin which is ascribed to them above. Whoever will take the trouble to look into the great work of Haller, will find him state distinctly, in as many separate sections, that the lymphatic vessels originate—1st, from the arteries, veins, and excretory ducts; 2d, from the cells of the cellular membrane; and, 3d, from the great cavities of the body. By the great cavities of the body, Haller does not mean the great membranous sacs, but the abdominal, thoracic, and cephalic cavities, in which those sacs are contained. He, however, states, in the most express terms, that the lymphatics originate from the surface of the serous membranes. Moreover, he ascribes to the lymphatics very nearly the same functions as are ascribed to them above—viz. to return a portion of the serum of the blood (vol. i. p. 256), and to take up the fluids effused into the cellular membrane and great serous cavities of the body (vol. i. p. 167). Farther, Haller regarded, as has been already said, the serum of the blood, the fluid exhaled into the great cavities and cellular membrane, and the lymph, as fluids of essentially the same nature. To this opinion I would subscribe, with the addition, that the serum of the blood and the serum of the membranes do not possess spontaneous coagulability, but when mixed together,

they form a fluid spontaneously coagulated, and in all its other qualities resembling the lymph.

3d. The third proposition need not detain us long; for, if it be granted that the serum of the blood and that of the membranes are introduced at the extremities of the lymphatics, it follows, as a necessary consequence, that these fluids must be blended together in their course through the lymphatic system, and must undergo whatever changes result from their reciprocal reaction. I shall here, however, endeavour to show that the disposition of the lymphatic vessels, and the structure of the lymphatic glands, are eminently adapted for mingling different fluids together, and possibly they may exercise this function of commixion on more fluids than we are at present aware of.

The distribution of the lymphatic system of vessels is obviously regulated by different principles from those that regulate the distribution of the other vascular systems. The division of the large arterial trunks, and the subdivision of their branches, is clearly intended to distribute the blood to every part of the body; the branches are uniformly smaller than the trunks from which they proceed, and though they may send off inosculating ramifications, still they proceed each to its separate destination. The same principle holds with respect to the distribution of the venous system, which is clearly intended to unite the small branches coming from every part of the body into larger branches, and these again into a few large venous trunks. In the disposition of the lymphatic vessels, the same principle is clearly recognized, since they are small at their origin, and becoming larger, at length terminate, most of them at least, in a single trunk. There is, however, obviously another principle by which the distribution of these vessels is regulated; they are continually dividing for no other purpose than again to re unite after communicating with the vessels running along side of them to the same destination, and the branches sent off are very generally of the same size as the trunks from which they proceed. This mode of distribution cannot, so far as I can see, be so easily explained as by supposing that it is intended to mingle thoroughly together the fluids circulating in the lymphatic vessels, and retard them in their course, so that they may have time to exert fully their reactions upon each other.

To mingle thoroughly together the fluids circulating in the lymphatic system, seems to be an object of so much importance in the human economy, that it is not entrusted, as in the bodies of many of the inferior animals, to the lymphatic vessels alone. A peculiar set of organs is superadded, viz. the *lymphatic glands.* The structure of those glands shows them to be essentially organs of commixion, and certainly no structure could be devised better adapted to answer that purpose. They may be regarded, according to the description of Mascagni, as altogether formed of a congeries of lymphatic vessels. The vessels which bring the lymph to the gland, and those which carry it away, may be represented as dividing each into an infinitude of small vessels, which resemble a net-work, from the frequency of their inosculations. The two capillary systems thus formed in the substance of the gland communicate with each other in two different ways—first, by the anastomoses of their extreme branches, and, second, by means of certain dilatations freely communicating with each other, which have been compared to the dilatations of the veins which occur in the erectile tissue of the penis. It must be obvious that this structure of the lymphatic glands is exceedingly well adapted for mingling together the fluids circulating in the lymphatic system, as well as producing such a slowness of circulation or stagnation of those fluids as may promote whatever reaction may be necessary for their intimate combination with each other. I am the more inclined to adopt the opinion here stated—that the lymphatic glands are organs of commixion, as I have never seen any theory suggested of the function of those organs which gives a satisfactory explanation of any useful purposes they serve in the animal economy.

I have only farther to remark with respect to the chyle, that there seems to be the same solicitude on the part of nature in mixing together the chyle and the lymph that there is in mingling the constituents of the lymph with each other. The chyle is absorbed by lymphatic vessels, and passes through lymphatic glands; for these vessels and

glands, when not engaged in carrying chyle, carry lymph, like other branches of the lymphatic system. Moreover, when the absorption of chyle is going on, there is a free intercommunication between the chyliferous lymphatics and those carrying transparent lymph; so that the former, inspected in the living body, are described by Haller as often seen emptying themselves of chyle, and filling themselves with transparent lymph. In this way the chyle, in its course to the thoracic duct, is mixed with the lymph coming from the lower extremities and abdomen, the mixture being begun by the inosculation of the chyliferous with the common lymphatic vessels, and completed in the substance of the lymphatic glands.

It seems to me probable that it is to this mixture that the chyle owes its property of spontaneous coagulability—such as we find it to possess when drawn from the thoracic duct. We do not, indeed, possess any certain data upon this subject, as the fluid, in the state in which it is extracted by the lacteal vessels from the chyme, cannot be obtained for examination. It is obvious, that when we extract chyle from the lacteals nearest the intestine, we can have no certainty that it is not mingled with membranous serum absorbed from the outer surface of the intestine, or from the mesentery, or with sanguineous serum transmitted from the capillary arteries. The researches of Tiedemann and Gmelin, however, render it certain that the chyle extracted from vessels just emerging from the intestines, differs in its qualities from that extracted from vessels emerging from the lymphatic glands. The chyle obtained from the former vessels is comparatively little coagulable, and in some of their experiments did not coagulate at all. It is also, for the most part, of a white colour, although varying in that respect according to the kind of aliments used. The chyle, again, obtained from the latter vessels, is highly coagulable, and the coagulum has generally a reddish colour, so as sometimes even to emulate the hue of perfect blood. Now this red colour is beyond all doubt derived from the admixture of lymph into the chyle. Accordingly, the distinguished physiologists mentioned above, who must be looked upon as the highest authorities upon this subject, embrace the opinions that the fibrin contained in the chyle, and on which its coagulability depends, is derived from its being mingled with lymph in the lymphatic glands. We may here advert to the opinions advanced by the same physiologists, that the colouring matter which gives the red tinge to the chyle is a secretion prepared in the spleen and the lymphatic glands, and that the fibrin derives its origin from albumen modified "by the numerous and diversified actions going on in the living organism." These opinions do not accord with those stated above; but it would be here out of place to discuss them. We shall only add farther, that if it be true that the chyle, as first absorbed from the intestines, is a fluid containing albumen, but without spontaneous coagulability, and that this fluid afterwards becomes spontaneously coagulable from admixture with the lymph, there is in the phenomenon some analogy with what was observed in the experiments mentioned above, in which fluids not spontaneously coagulable, like milk and the albumen ovi, concreted into a buffy coat when mixed with blood flowing from the vein.

[To be continued.]

OBSERVATIONS ON THE FATTY MATTER OF THE BLOOD.

To the Editor of the Medical Gazette.

Sir,

Should the following observations on the fatty matter of the blood be considered sufficiently interesting, I shall feel obliged by their early insertion in the pages of your valuable journal.

I am, sir,
Your obedient servant,
Golding Bird, F.L.S. &c.

44, Seymour Street, Euston Square,
April 12th, 1836.

There is, perhaps, no subject connected with animal chemistry, on which more discrepancy of opinion has existed, than on the true nature of the different forms of fatty matter; and of these the fatty matter of the blood presents probably the most interesting features. This substance is found in the serum as well as in the crassamentum of blood, and adheres with so much tenacity to the albumen and fibrin, even after they have been repeatedly washed with warm water to free them from any adherent

red particles, that some chemists have been induced to suspect that something like a chemical combination existed between the fat and albumen or fibrin.

The fatty matter is found in the crassamentum (mixed up, or perhaps combined with, the fibrin and red particles) in a larger proportion than in an equal weight of serum, combined with albumen. From Lecanu's experiments (*Journ. de Pharm.* Sept. 1831,) it appears that 1000 grains of venous blood contain 3·74 grains of fat, and of this quantity 1·31 grains may be regarded as elain, and 2·43 grains as stearin; and that the same weight of healthy serum contains 2·20 grains of fat, consisting of 1·0 grain elain and 1·20 stearin. From my own experiments I should conclude, that the proportion of fat, stated by Lecanu as existing in serum, is much above the average quantity: in three different specimens of fresh serum, of apparently healthy blood, I found the quantity present in 1000 grains to be 1·30, 1·60, and 1·20 grains respectively; it sometimes happens that this quantity is far exceeded; but this increase ought to be considered as a deviation from the normal state of the blood. A remarkable example of this occurred lately, in the female clinical ward of Guy's hospital, in which a woman, affected with well-marked diabetes insipidus, was bled from the arm, in a few hours, the blood had separated perfectly, the crassamentum was firm and contracted, but the serum resembled so much milk; some of this was decanted, and, in a short time, a layer of a cream-like substance appeared on the surface, which, when removed and agitated with æther, nearly entirely dissolved: this ethereal solution was of a golden yellow tint, and by spontaneous evaporation, yielded minute crystals of stearin mixed with the more fluid fat or elain: the total quantity of fat yielded by 1000 grains of this serum amounted to nearly 5·30 grains. A similar milky state of the serum has been observed in blood drawn shortly after a hearty meal, as was shown long ago by Dr. W. Fordyce (*Inq. into the Cause, &c. of Fever*, 1774, page 24), and has been supposed to depend upon an imperfect admixture of chyle with the blood; whatever may be the *cause* of this milk-like serum occurring, the physical explanation of its turbidity depends upon a considerable excess of fatty matter, forming a kind of imperfect emulsion with the albuminous and alkaline constituents of the serum.

The readiest mode of obtaining this fatty matter in sufficient quantity for examination, is by coagulating about a pint of serum (as free as possible from red particles) by means of a salt-water bath, breaking up the coagulum, and digesting it in repeated portions of boiling water, for the purpose of removing as much saline matter as possible, draining the insoluble portion on a piece of muslin, and then boiling it for a few minutes with strong alcohol or *pure* pyroligneous æther: the whole being thrown on a filter, previously moistened with a little alcohol, so as to pass through as quickly as possible, the filtered fluid on cooling deposits a little stearin, and, by gentle evaporation, a considerable quantity may be obtained; the elain being much more soluble, remains in the fluid after the deposition of the stearin, a second crystallization will be required to render it colourless: from the quantity of serum above mentioned, about 8 grains of tolerably pure stearin may be obtained.

A more simple (but less economical) mode of separating the fat from the serum, is to agitate the latter with sulphuric æther in a closed tube, and allow the mixture to repose; in a short time a fine yellow æthereal solution of the fat will rise to the surface, and may be decanted or removed by the pipette: this, by spontaneous evaporation, yields crystals of stearin mixed with elain. If a portion of the stearin prepared by either of these processes is dissolved in a small quantity of hot alcohol, and allowed to crystallize, some of the fat will be found to assume the form of plates, bearing, as some have supposed, no distant resemblance to cholesterine, or the fatty matter of the bile, which analogy appears at first sight to be strengthened by the facts that these crystals, on being immersed in strong sulphuric acid, assumes a fine pink colour, (which cholesterine is well known to do) and further, that they are not saponifiable by caustic alkalies. But over this latter circumstance, I have good reason to believe, there hangs an important source of fallacy, which becomes the more important, as it, in conjunction with the plate-like form of the crystals, and the re-action of sulphuric acid, has given rise to an idea lately

promulgated, (amongst others, I believe, by M. Denis) of the presence of cholesterine in the blood, as one of its normal constituents. I shall, therefore, attempt, as briefly as possible, to explain what I believe to be the true nature of these fatty crystals, and the cause of those peculiarities which have induced some chemists to suppose them to be composed entirely, or in part, of cholesterine.

Reflecting upon the entire insolubility of cholesterine in liquid caustic alkalies, I concluded that the best, and, indeed, only satisfactory mode of ascertaining its presence, would be by boiling the fat of blood in a pure alkaline solution, which would dissolve the elain and stearin, leaving the cholesterine untouched. Acting upon this idea, I prepared a considerable quantity of the fatty matter of the blood, and boiled it in a solution of pure soda for some time. An equal bulk of water was then added, and the whole allowed to cool. In a few hours a white and somewhat granular deposit had taken place, the supernatant fluid being quite limpid, and strongly alkaline, depositing a mixture of oleic, margaric, and stearic acids, after super-saturation with hydrochloric acid. The white deposit, from which the alkaline solution had been decanted, was washed with cold distilled water, in which fluid it appeared quite insoluble. A portion was then boiled in alcohol (specific gravity ·815), in which it readily dissolved, forming a limpid and colourless solution. On cooling it deposited numerous crystalline plates, possessing a pearly lustre. These crystals were soluble in æther, and when placed in strong sulphuric acid they assumed a deep orange-red tint, in all which circumstances they resembled cholesterine; but the following facts will serve to prove that this resemblance, however apparently close, is really fallacious, and depending upon a very superficial examination.

When the pearly crystals, obtained as above mentioned from this alcoholic solution, are exposed to heat in a platinum spoon, they fuse, catch fire, and burn with a large smoky flame to a white ash, which is *strongly alkaline, and effervesces with dilute acids*, and consists almost entirely of carbonate of soda. From this experiment it appeared probable that the supposed cholesterine was really nothing more than a combination of a fatty acid with an alkali. To determine this with certainty, some of the pearly crystals were dissolved in warm alcohol, and dilute sulphuric acid added guttatim, until no increased troubling ensued, arising from the deposition of sulphate of soda (formed by the union of the sulphuric acid with the soda existing in a state of combination with the fatty matter dissolved in the alcohol); which being allowed to precipitate, the whole was warmed, and the supernatant fluid decanted and evaporated over a vapour bath. The crystals thus obtained by evaporation were fine white needles, soluble in æther and alcohol, fusing, and then inflaming, on the application of heat, leaving not a trace of ash behind: the alcoholic solution of these crystals faintly reddened tincture of litmus. From these, as well as other circumstances which it is unnecessary to recapitulate, it was evident that these crystals consisted of nearly pure stearic acid; and that the pearly plates (resembling cholesterine), deposited from the alcoholic solution before the separation of the soda by sulphuric acid, were bi-stearate of soda, which Chevreul (*Sur les Corps Gras*, 1823) more than thirteen years ago, described as possessing a peculiar pearly lamellated appearance, and which certainly, on a superficial examination, resembles cholesterine very closely.

I am aware that an objection might be raised against the explanation I have offered, of the composition of the supposed cholesterine, on the ground that crystals resembling that principle are (as I have already mentioned) deposited from the alcoholic solution of the fatty matter of blood before the *artificial* addition of any alkali; but this crystalline deposit has been shown, by Berzelius (*Traité de Chimie*, vol. vii. p. 47) to consist of a combination of a fatty acid with an alkali naturally existing in the blood (stearate of soda), and hence it yields an alkaline ash on incineration.

If these observations are deemed sufficient to prove that cholesterine cannot be regarded as one of the constituents of healthy blood, it must follow that if ever it is detected in that fluid, it must be regarded as anormal; but, even in disease, I believe it to be of rare occurrence. I once, however, detected its presence (in a state of minute effusion) in the blood of a patient in Guy's Hospital, affected with acute icterus, com-

plicated with pneumonia and pleurisy, under the care of Dr. Addison. The serum of this patient's blood possessed a greenish-brown tint, and even tasted bitter after concentration: quantitative analysis proved it to consist of

Water	898·0
Albumen (including earthy phosphates)	92·40
Cholesterine	1·40
Fatty and biliary matter	2·20
Peculiar extractive and lactates	3·0
Alkaline carbonates, phosphates, and hydrochlorates	3·0
	1000

RAVAGES OF THE SCURVY,

ON BOARD THE "LADY JANE."

To the Editor of the Medical Gazette.

Sir,

Should you deem the following particulars, respecting the crew of the Lady Jane, whaler, of Newcastle, interesting, or in any respect worthy the attention of the profession, their insertion in your journal will oblige,

Your obedient servant,
James Williamson.

North Shields,
April 6th, 1836.

On the 14th March, 1835, the ship Lady Jane sailed from the Tyne, with a crew of twenty-six men, including officers and surgeon, intending to call at the Orkneys to complete her crew, by shipping twenty-six additional hands, making up the full complement of fifty-two. After a fine run of three days, we arrived at Stromness on the 17th, and having obtained the requisite number of men, sailed from that place on the 23d of the same month. At noon, on the 19th of April, we made the ice in latitude 62° 30′ N., where we were detained three or four weeks, endeavouring to procure fish; but, being frustrated in our attempts, we proceeded thence up the east side of Davis' Strait, as far north as lat. 72° N., with the intention of sailing round its north-west boundary, the usual fishing ground, in which further intention we were disappointed, by the ice not coming down as usual; when, on July 13th (having previously obtained one fish), we proceeded south, and on the 26th made the west land in lat. 68° 37′ N. Owing to a compact body of ice lying in that direction, we were prevented from a passage northwards, but continued in that latitude, made fast to the land-floe, in expectation of the ice opening, instead of which we became beset, and, with the exception of a few days in September, remained so until our liberation on Friday the 19th of February, 1836.

From the time of leaving the Tyne until the 10th of December we had little sickness on board, with the exception of one man labouring under phthisis pulmonalis, who died on that day, and it was not before the 23d of the same month that the first symptoms of scurvy began to manifest themselves among the crew, now dispirited by our long confinement, and the liberation of all the ships in company at one time, amounting to eight. From this period sickness increased amongst us, many abandoning themselves to despair, unable to take proper means for preserving cleanliness, and refusing to take any regular exercise. The cold, which from the time of being beset gradually became more intense, was, on the 22d of November, at 17° below zero of Fahrenheit, after which date we were accidentally deprived of the use of the thermometer. From the time of leaving port until the 5th of October, excepting about a fortnight in August and September, the crew had full allowance of provisions, consisting of 2 lbs. of beef or 1¾ lbs. of pork daily, together with pea-soup five days, and pudding on the other two of the week, beer while it lasted, and a liberal allowance of rum, finished about Christmas,—bread was allowed *ad libitum*. It should also be stated, that in addition to the ship's allowance, the men had their private stocks of tea, coffee, sugar, tobacco, &c., which were mostly expended by November. Water was procured by melting the snow off the ice, which latterly was strongly impregnated with salt.

On the 5th October, it was considered necessary to husband the stock of provisions, and every person on board was put on reduced allowance; consisting of half the above stated quantity of animal food, of pea-soup, pudding, &c., out of which the crew had to maintain twelve men belonging to a wrecked ship, and of nearly 3 lbs. of bread per week each man. Our vegetables, consisting of potatoes and turnips, occasionally given

out to the ship's company, were finished about September.

The first symptoms of the disease, which afterwards destroyed so many of our men, were as usual, tenderness of the gums, attended with a fœtid discharge, succeeded by a petechial eruption on the lower extremities, with œdema, stiffness of the ham-string tendons, and a general rigidity of the muscles. Passive hæmorrhage took place from the mucous membranes, varying according to the idiosyncrasy of the individual. In most cases were bloody stools, bleedings from the urethra, hemoptysis, and bleedings from the nose. The appetite was generally good, and when the patient was in bed he complained of no pain or uneasiness, excepting debility and dyspnœa, which on the slightest motion became extremely urgent. The men did not seem aware of their weakness, and indeed the utmost caution in moving them was necessary, after having been a few days in bed, several having fallen into fatal syncope on attempting to rise. In general the bowels were relaxed, but in other cases obstinately constipated. The pulse was somewhat slower and more feeble than natural. In this manner the disease generally advanced to a fatal termination, apparently the consequence of exhaustion. The whole crew were more or less affected with this disease; and up to our arrival at Stromness, on the 12th of March, 1836, twenty-two deaths had occurred on board. Subsequent to this period, five men died at the hospital provided by Captain Ross, under the care of J. M. Hamilton, Esq.

The last accounts from Orkney state that the remainder of the crew are convalescent.

TREATMENT OF HYDROPHOBIA.

To the Editor of the Medical Gazette.

Sir,

I have been much interested by Dr. England's case of hydrophobia, in your journal of last week. In a disease so truly horrible, any recommendation may be deemed admissible; and under this impression I send you these few lines, which may perhaps find a place in your valuable columns. In the above case, the chief mischief was referred to the *pharynx*, and the patient herself said, "that she would be quite well *if she could swallow*." Now it has struck me that on future occasions, where the spasm of the pharynx is so intense, it would be advisable to remove the cuticle at once, by the liquor ammoniæ, from the front of the neck, and then apply morphine immediately to the abraded part. The spasm may thus be reduced, and a further facility given for the introduction of one of Read's or Jukes's tubes into *the stomach*; whereby both the proper medicines and nourishment may be given to the patient. In this county there is a popular prejudice for *dipping* any unfortunate sufferer who has been bitten by a dog supposed to be mad. The mouth of the Severn is, I believe, the favoured place, and the process must be undertaken immediately or soon after the accident, no matter what be the time of year. A patient of mine, from Staffordshire, has lately informed me that several people were bitten last year, in his neighbourhood, by mad dogs, to whom the Ormskirk (is that the name?) medicine was given *effectually* as a preventive. However, we had better take all these stories *cum grano salis.*—I am, sir,

Your obedient servant,

Gloucestrensis.

April 12, 1836,

CASE OF INFLUENZA.

PROFESSIONAL COURTESY AND FAIR DEALING.

To the Editor of the Medical Gazette.

Sir,

I shall feel obliged by your inserting, in some corner of your periodical, the following case, with remarks regarding its nature and treatment, by Dr. Nicol, one of the surgeons to the Northern Infirmary at Inverness, and author of several excellent papers published in the Edinburgh Medical Journal. I should not have considered it sufficiently important for publication had it not given rise, in this quarter, to much disagreeable and unjust animadversion; and my first intention was to let it pass unnoticed, as all medical men are liable to be more or less exposed to such attacks.

I cannot for a moment suppose that the highly respectable medical gentleman with whom I consulted could give the slightest countenance to such aspersions, even if we had differed widely in opinion. None but the avowed charlatan makes pretensions to infallibility, and none but the ignorant or the foolish are deceived by those pretensions. Every candid medical man will readily acknowledge that he has often been mistaken; hence the advantage of consultations: and it would not be very creditable to the members of a liberal profession, were they, in order to establish their own reputation, to avail themselves of every paltry triumph which accident or even superior tact might afford them over a less fortunate brother. He who is found in the right to-day, may be found in the wrong to-morrow; but I do not intend to insinuate such a charge against the members of the medical profession in this quarter—indeed, I do not intend to impute bad motives to any one. The origin of the animadversions alluded to is certainly somewhat obscure, but I am disposed to attribute it chiefly to senseless gossip, which passing, of course, through a variety of media, has at last become fully charged with a highly noxious power. I have been induced to send these communications to the MEDICAL GAZETTE, because it is very generally read by the medical practitioners in this part of the country.

I am, sir,
Your obedient servant,
JAMES SYME.

Alloa, April 14, 1836.

Mr. —— was seized, on Sunday, the 25th January, 1836, with slight rigors and other febrile symptoms. He is a young man, rather thin, pale complexion, and of nervous temperament. He bathed his feet, and took a quantity of warm gruel at bed-time. He perspired very freely during the night, and on Monday morning Mr. S. was called to see him. He complained of great languor, severe headache, pain in the back, total loss of appetite, and intense thirst. He had vomited a little, and felt constant nausea. His pulse was upwards of 120, rather small; breathing quick; tongue coated with a thick brown fur; skin moist. An emetic was prescribed, which brought up a large quantity of bilious-looking matter. He afterwards took a dose of castor-oil, which brought away several dark-coloured stools. At bed-time he took a small dose of calomel, with a few grains of Dover's powder. The patient had previously complained of a cough, for which he had been using a squill mixture. The cough had now become more severe, and he still occasionally used the mixture. A Seidlitz powder was prescribed in the morning, and several stools, similar to the former, were passed in the course of the day. The cough had increased in severity, with some difficulty of breathing, but without pain in the chest. A quantity of leeches were applied to the chest, which bled freely. A blister was afterwards applied to the breast. At bed-time a dose of calomel and Dover's powder was again prescribed, and a Seidlitz powder in the morning, which was again followed by dark-coloured stools. The pulse had now become less frequent; the tongue cleaner; the bowels considerably improved; and the headache entirely removed. A wheezing cough, with some difficulty of breathing, still continued, attended with a moderate expectoration of frothy mucus, and the patient still complained of pain along the back, and felt very weak. At this period, being the fourth day from the attack, another medical practitioner was called in, and a solution of tart. antim. was prescribed, to be given at intervals, as far as the stomach could bear, which was continued for two or three days, and the squill mixture was again resumed.

The bronchial affection disappeared in about eight or ten days from the commencement. The patient has since been slowly and gradually recovering, but has not yet been able fully to resume his ordinary duties with his former activity, and still complains of weakness.

Alloa, April 1, 1836.

P.S. The above case having been written from memory, is not so complete in all its details as it otherwise might have been, but the outline is sufficiently correct and intelligible.

Inverness, April 12, 1836.

DEAR SIR,

I have been severely indisposed for some days, which must plead my apology for not replying to your esteemed communication sooner. The case which

you submit for my opinion is that description of influenza which has only been noticed in this country within the last few years. I am at this moment labouring under a second attack, and I regret to say that, in despite of every care and treatment, I progress very slowly in the way of amendment. The febrile symptoms and headache disappear in a few days, but the jaundiced feelings, unwillingness to work, loss of appetite, languor, and pain in the back and loins, with distressing cough, continue for weeks, and sometimes for months, resisting even mitigation from every description of treatment. I have many such cases here at present, and for your satisfaction beg to say, that the febrile symptoms are usually subdued after the manner narrated in your case; but he who expects that the sequelæ are to vanish immediately after the former have been subdued, however wise and well-directed his treatment may be, I fear will, in ninety-nine times in the hundred, be wofully disappointed; at least this is consistent with my experience; and I have tried ipecacuan, squill, calomel, tartar emetic, digitalis, opium, and colchicum, in all forms and mixtures, with little advantage. The subject of your case will be weak in the back, as well as generally, and have cough for a considerable time; at least this is my impression, and in place of censure, he should only be extremely grateful for the course you pursued.

You are quite at liberty to publish my opinion, only take care you publish the case exactly as it has been transmitted to me along with it.

I am, dear sir,
Yours very faithfully,
(Signed) John Inglis Nicol.

James Syme, Esq.
Surgeon, Alloa.

PURPURA HÆMORRHAGICA,

ATTENDED WITH MORTIFICATION AND LOSS OF THE FOOT.

To the Editor of the Medical Gazette.

Sir,

Will you have the goodness to insert the following case of purpura hæmorrhagica in your valuable journal, as it is the only one in which I have seen the loss of a limb from this disease.

I remain, sir,
Your obedient servant,
C. J. B. Aldis, M.A. M.B.
Inceptor Candidate of the Royal College of Physicians.

13, Old Burlington-street,
April 16, 1836.

John Tyrrell, æt. 38, coachman, admitted into St. George's Hospital, Sep. 21, 1831. Complains of "cold and cough, with fever;" very weak; sore throat, with superficial ulcerations on the velum pendulum, at the base of the uvula; deglutition difficult; pulse and skin natural; tongue clean; bowels costive; urine free.

His complaint began on Thursday week, with shivering and cold.

22. Bowels opened by the medicine; better.

24. Head and breathing oppressed yesterday; throat much relieved.

26. Abundant petechial eruption over the legs, which appeared on Saturday morning; griping pains in the stomach, with sickness; urine not free.

28. "Very bad these two nights;" has been sick. Bowels open; tongue white; pulse 100, oppressed.

30. Blood slightly buffed, of average firmness; sickness better. Pulse oppressed, 90; felt faint after the bleeding. Several clusters of vivid petechiæ appeared this morning about the elbows, arms, and knees; "has been less oppressed in the chest since they came out;" bowels not open to day.

Oct. 1. Feet very cold.

3. The eruption has nearly disappeared from the legs, but the right foot is covered with it (purpura), and is very sore. Pulse 90; tongue brown and dry; bowels not open.

6. Better, excepting the foot, for which *videat chirurgum.*

Note.—The foot has assumed a dark gangrenous character.

10. Slight discharge from the foot.

15. The cuticle of the foot is extensively detaching itself, and exposing the cutis in a brown and moist condition; it became painful last night, until the bed-clothes were supported by frame work.

22. Fresh appearances of petechiæ in the upper and inner part of the right thigh.

24. Still further effusion of petechiæ in the upper part of the right thigh, and also in both wrists.

27. The petechiæ, which had appeared in considerable number about right groin, are fading away, as well as the discoloration of both wrists.

He was transferred to the surgeon. The tarsus and phalanges of the right foot separated spontaneously, no ligature being required for any blood-vessel; the os. calcis remained. I accidentally met him a year after he left the hospital. His health was perfectly good, and he walked with the aid of crutches.

GERMAN MEDICAL INSTITUTIONS

HOSPITAL OF MUNICH.

To the Editor of the Medical Gazette.

Sir,

Munich is comparatively a healthy city, and is not subject to any specific endemic disease: situate 1700 feet above the sea, in an extensive plain, bounded southward by the chain of Tyrolean Alps, its atmosphere is light and dry, owing to which cause, to the cleanliness of its streets, and to the absence of abject poverty among its inhabitants, it is remarkably free from intermittent and typhoid fevers; notwithstanding an extensive tract of marshy and boggy land in its neighbourhood. To the same causes is ascribed its exemption from scrofulous affections, which are rarely seen in the inhabitants of the town; most of those in the hospital having been sent from the country. The most prevalent diseases during last autumn and winter have been fever, complicated with nervous and gastric irritation, erysipelas, and diarrhœa, with which last the greater number of patients in the hospital have been affected, and this disposition still continues in a modified degree, although within the last few weeks thoracic inflammation and bronchial irritation have also been extremely prevalent.

The practice resembles that of the older physicians; and the ancient nomenclature of diseases is not yet superseded by that based on pathological anatomy. The treatment is not exclusive, being grounded on existing indications, and varied according as the peculiarities in individual cases appear to require. Baths and enemata are but little employed, auscultation and percussion are not used, except now and then by Dr. Ringseis, professor of clinical medicine, whose examinations of patients and clinical discourses are minute and methodical, and whose diagnosis is generally very accurate. Other innovations of the French school, as the endermic method, lithotrity, the use of the speculum vaginæ, &c. have not been adopted. In one patient with a tumor occupying the greater part of the hypogastric region, who had been several weeks in the hospital, and whose case was considered to be exceedingly obscure, no manual examination, *per vaginam*, had been made, although the case appeared to me to be one of hypertrophy, or polypus of the uterus. Blood-letting, which was formerly in very general use, is now, comparatively, rarely employed; but in lieu thereof, antimonials, counter-irritants, and evacuants, are had recourse to,—leeches are, also, but seldom used. The reason assigned for this alteration is, that the medical constitution of Munich has very remarkably changed within the last six or seven years, inflammatory diseases requiring the abstraction of blood being much less frequent.

Among the remedies most in request are, emetics, which have lately been used with very great effect in gastric disorders and diarrhœa; tartarized antimony, in large and small doses; the decoctum antiphlogisticum, which consists of nitrate of potass, oxymel, and decoction of mallows; mild purgatives, especially the sulphate of potass in infusion of rhubarb, and infusion of rhubarb with ipecacuanha. Mercurials are not frequently given; except where evident hepatic derangement exists. Stimulants and bitters are often prescribed where no inflammatory action exists. The muriate of ammonia, the preparations of bark, the calamus aromaticus, are often employed in diseases indicating a want of tone; the former occasionally in sub-acute inflammation. In fever with gastric and biliary derangement, and in diarrhœa with vomiting or nausea, emetics are generally given at the commencement, and are succeeded by an infusion of rhubarb and ipecacuanha, or infusion of rhubarb with small quantities of sulphate of potass: where these are contra-indicated, the Liq. am-

mon. acet., salines, and, in some cases, the decoctum calami, are substituted; this treatment has been attended with great success. Erysipelas of the face, which is not uncommon at Munich, is generally treated in like manner, by emetics at the outset, and the subsequent exhibition of rhubarb, small doses of sulphate of potass, or tartarized antimony — a solution of supertartrate of potass being prescribed for ordinary beverage. Moderate bleeding, the tartarized antimony, and sinapisms, or blisters, are principally trusted to in combating thoracic inflammation; in which, however, Dr. Ringseis often abstains from bleeding, and gives large doses of tartarized antimony, which induce copious perspiration, and is generally followed by great relief. In bronchial inflammation and irritation, the tartarized antimony, sulphate of potass, ipecacuanha, oxymel, blisters, and hyoscyamus or cicuta in some demulcent mixture, are the remedies most frequently adopted.

The surgical and ophthalmic department of the hospital is superintended by Professor Von Walther, who combines, in most cases, internal remedies with the external treatment. Operations of importance, except cataract, are not of very frequent occurrence. Professor Walther usually operates by couching, and always prefers the keratonyxis, making the opening through the centre of the cornea, to the puncture of the sclerotic. Both the eyes of an old man were operated on in this manner a few days ago, and no unpleasant symptoms succeeded. The lateral operation of lithotomy was performed four days ago on a boy about ten years old; the stone was large, and some difficulty was experienced in its extraction. Peritoneal inflammation came on, which was treated by leeches to the abdomen, and by half-grain doses of calomel every two hours; this reduced the inflammation, and the patient is now going on well. The leg of another boy, about the same age, has been amputated by the flap operation within the last few days, for disease of the ankle-joint and bones of the tarsus. Exfoliation of a portion of bone was going on on the outside of the instep, but there was little swelling about the joint, the motion of which did not appear to be materially impeded, and the health of the patient was tolerable. Although I did not inquire particularly into the case, having only seen it once or twice before the operation, yet, from what I saw of it, I should have questioned whether the articulation were diseased to any extent. I was assured, however, that on examining the limb, the bones forming the joint were found to be carious: at all events, a case in that stage of disease would not have been considered to require amputation in the London hospitals. Among the other patients is a man, aged about 50, who was admitted some weeks ago with disease of the bladder, the nature of which was not well ascertained, but the leading symptom was the deposition of a quantity of muco-puriform matter in the urine. Injections with water, the application of moxa above the pubis, and other means, produced no amelioration, when, at my suggestion, the decoction of pareira brava was prescribed, and its exhibition was attended with great advantage, the urine becoming clearer, and almost entirely ceasing to deposit matter in the space of a few days.

There have lately been several cases of fracture in the hospital. Those of the leg are generally treated on a suspended frame, with moveable footboard, the limb being maintained in the same line as the body, on its posterior part, and the knee slightly flexed. No lateral splints are used, and the only bandages are those fixing the foot, and a narrow strip or two below the patella, which are quite insufficient to keep up a proper degree of counter-extension. In some simple fractures, the leg is placed between thick cushions of bran and splints extending its whole length, the foot being unsupported by a foot-board. In compound cases, simple dressings are generally used: bladders of ice are attached to the frame, and rest nearly their whole weight on the limb. The same means is had recourse to in injuries of the head in preference to cold lotions. A man, with fracture of the thigh, just below the trochanters, has been in the hospital about three weeks: when admitted, there existed considerable swelling about the hip, on which account no apparatus was applied, nor has any thing further been done beyond fixing the foot to the bottom of the bed, the limb being kept in the extended position, notwithstanding the swelling has subsided; there is consequently considerable shortening. I

am informed, however, that Dessault's long splint is generally applied in fracture of the thigh. In fracture of the bones of the fore-arm, splints appear to be seldom used: the arm is laid on a pillow in pronation; a strip of bandage passing round the upper forearm, is fixed to the edge of the pillow, and a similar strip passing round the wrist, is brought in a contrary direction, and fixed to the opposite edge of the pillow. Patients with this accident must therefore necessarily remain in bed until consolidation is effected. I am unable to say what are the results of this treatment.

EDWIN LEE.

Munich, April 3, 1836.

Abstracts of Cases from the Clinique of DR. RINGSEIS.

Intermittent fever.—A woman, æt. 30, admitted No. 3, on account of a quotidian attack of ague, which she had had twelve days previously. She was ordered Ant. Tart. gr. ¼, Potassæ Sulph. ʒii., four times a day during three days. This produced sweating, and copious stools, and on the 5th she had no recurrence of the attack. She was prescribed on the 6th, the mistura amara, which is composed of Ext. Taraxaci, Ext. Gentianæ, and Infus. Trifolii, with a small quantity of Tinct. Aloes; was allowed a meat diet, and having had no return of the paroxysm, was dismissed on the 12th.

Fever.—A woman, aged about 32, admitted 2d Nov., with fever, vomiting, and general derangement of the digestive apparatus: an emetic of tartarized antimony was prescribed, after which the most urgent symptoms ceased. A solution of supertartrate of potass was ordered as an ordinary drink. On the 5th, the mistura amara, with Tinct. Rhei, was prescribed, and on the 8th the patient was sufficiently recovered to be dismissed the hospital.

Fever and diarrhœa.—A middle-aged woman, admitted at the end of October, with fever. Colic pains all over the abdomen, which was tender on pressure, and diarrhœa. She was ordered to take during the first three days ʒii. Magn. Sulphat. four times a day. By this the symptoms were relieved. A mixture of Infus. et Tinct. Rhei was then prescribed, and on the 7th, as the bowels were confined, Ipecac. pulv. gr. ¼, Pulv. Rhei, gr. ii., every two hours. She became gradually better, but on the 10th had nausea, and vomited, for which an emetic of tartarized antimony was ordered; convalescent on the 12th.

Pleurisy.—A young man of plethoric habit, subject to catarrh, was admitted on the 10th Nov., with an attack of pleuritis. The pain in the side was very acute; the breathing laborious; headache; pulse 100, firm, contracted; skin hot; bowels relaxed. Sinapism to the painful part of the thorax: a mixture of Decoct. Althææ, Mucilage, Potassæ nitratis, and Ant. Tart. gr. ½, four times a day. By these means the urgent symptoms were relieved on the 11th, when a blister was applied, which was the only thing the patient complained of, two days after.

Pleuro-pneumonia.—A young man, who had previously laboured under symptoms of phthisis, was admitted on the 26th October, with pleuro-pneumonia on the left side, accompanied with high fever, headache, and diarrhœa. During a paroxysm of coughing, a vomica burst, and a quantity of matter was discharged; pectoriloquy was distinctly heard on the upper part of the left side of the thorax; bleeding to ten ounces; a mixture, composed of Potass Nitr. Ant. Tart. et Decoct. Altheææ. On the 29th, patient was much better; an emetic of tartarized antimony; sinapism to affected side of thorax. He went on improving till the 6th November, when he was allowed chicken and soup, and the bowels being constipated, was prescribed Tinct. Rhei, ʒii., in divided doses, every day. After the inflammatory symptoms had subsided, he had still cough, and muco-puriform expectoration.

Acute rheumatism.—A woman, æt. 32, admitted 1st Nov., having been ill five days. She had high fever, pain in all the limbs, some of the joints, especially the ankle, being swollen, and tender to the touch. A mixture, containing tartarized antimony and sulphate of potass, was prescribed; to this the nitrate of potass was subsequently added. On the 3d, pains but little alleviated; temperature of skin high; pulse quick, and rather full; breathing oppressed, and hurried; tongue coated. Auscultation furnished no unusual signs. Abstraction of ten ounces of blood from the arm, by which she felt greatly relieved. On the 4th, she was ordered half a grain of tartarized antimony in infusion of rhubarb, four times a day:

this produced five actions of the bowels, and the amelioration continued. On the 7th, there was but little febrile action; the pains were greatly alleviated; the breathing natural, and she slept better at night; but the tongue was still much loaded; same medicine continued; broth diet. She was ordered on the 9th, a mixture composed of ipecacuanha and infusum sambuci, which occasioned profuse sweating; the bowels had acted freely during the last few days; and she found herself much better. Increased action of the heart, oppression of breathing, heat of skin, came on on the 17th, when she was ordered half a grain of calomel, the same quantity of digitalis, and a quarter of a grain of opium, eight times within the four-and-twenty hours. The following day these symptoms had nearly disappeared: a solution of supertartrate of potass was then directed to be taken as an ordinary beverage: she experienced no further impediment to her recovery, which took place about the end of the month.

OF THE

NERVES SUPPLYING THE CAVERNOUS STRUCTURE OF THE PENIS,

AND THEIR CONNEXION WITH THE HYPOGASTRIC PLEXUS OF THE SYMPATHETIC.

By Professor Mueller, of Berlin*.

After I had discovered the fact that the arteriæ helicinæ—the branches of the arteria profunda penis producing erection — were different from those branches of the same vessel which served for nutrition (see Medical Gazette, January 9, 1836), I put to myself the question, whether the nerves of the penis were of the same or different properties, whether they belong to the system of nerves of animal life alone, or whether they also included organic fibres? Do those nerves upon which the sexual gratification depends differ in their nature from those which produce the accumulation of blood in the corpora cavernosa?

I have been so fortunate as to find, both in man and the horse, that the nerves of the cavernous bodies are made up both of branches proceeding from the organic as well as the animal system, whilst the nerves of animal life alone provide the nerves of sensation of the penis.

Since, by the discovery of the arteriæ helicinæ in the corpora cavernosa penis, the immediate source of erection is found to be in these bodies themselves, so will it be also proved, if such a connexion exists between the nervus sympathicus and the nervi cavernosi, that the sympathicus performs the principal part in the phenomenon of erection. I have observed that by far the greatest number of the nerves which penetrate the corpora cavernosa in man, derive as considerable fibres from the organic as from the animal nervous system, and that the same takes place throughout the nerves supplying at least the posterior half of the corpora cavernosa of the horse, whilst the anterior half is supplied only by nerves arising from the animal system, and entering anteriorly to the pubes—viz. the branches of the nerv. pudendus, given off whilst passing along the dorsum of the penis. Therefore the posterior nerves, which penetrate the corpora cavernosa behind, and enter the symphysis pubis, are composed as well of branches of the nervus sympathicus, proceeding from its plexus hypogastricus, as of the branches which come from the nervus pudendus communis.

Upon the side of the urinary bladder in the horse, and proceeding towards its neck, are many fine twigs of the plexus hypogastricus, which often join one another on their way, and separate again, forming a net-work. In this part of the plexus hypogastricus, upon the side of the middle and anterior part of the bladder, lie several small ganglions, separated from one another more or less, but often by a considerable space; they measure from one-half to two or three lines in diameter. From these ganglions twigs pass into the urinary bladder, by which means the grey nervous fibres destined for the corpora cavernosa pass from the hypogastric plexus thither, and they then unite again in the same reticulated manner. Before these nerves arrive at the posterior surface of the pubes, they unite in the neighbourhood of the neck

---

* Revised for this journal by the learned Professor himself.

of the bladder with branches of the nervus pudendus. Through this anastomosis are formed many strong nerves —the *posterior cavernous nerves;* it is of these alone that I now treat.

Many of the nerves formed in this manner, of which, in the instance now before me, I reckon four large and two smaller, pass under and behind the symphysis pubis, and penetrate the corpora cavernosa, in part accompanying the arteria profunda penis, and partly in other places.

I remark particularly, that neither the posterior cavernous nerves, nor the anterior branches of the nervus dorsalis penis, form any swellings in their passage through the fibrous coat of the corpora cavernosa. In man, a much greater portion of the cavernous nerves are in connexion with the hypogastric plexus, and the number of twigs which come from the nervus dorsalis penis *alone*, is much smaller than in the horse. Hitherto, only the cavernous twigs of the nervus dorsalis have been known.

The demonstration of this communication in the horse is so easy, that the principal points may be clearly made out in a few weeks; but the preparation of those of the cavernous nerves, which anastomose with the hypogastric plexus in man, requires an extraordinary degree of patience, and a satisfactory demonstration of them, together with the hypogastric plexus, can only be perfected in the course of some months. The larger of these cavernous nerves can be found easily before and under the symphysis pubis, after these bones have been very carefully cut away; but the difficulty is, to demonstrate their connexion with the plexus hypogastricus.

In the summer of 1834 I was following out the twigs given to the penis by the nervus dorsalis, which I, as well as other anatomists, thought were the only nerves this organ received, and by this means I discovered, upon the root of the penis, a considerable number of grey nervous fibres, which passed forwards in a kind of lace-work between the vasa dorsalia from the right and left side, in order to unite themselves almost immediately to the branches of the nervi dorsales; some, however, pierced the root of the penis directly. As I prosecuted the dissection of these grey fibres backwards, I was quite astonished to find that the stems did not arise from the nervus dorsalis, but were continued in a diverging direction backwards to the sides of the commencement of the prostate gland, and underneath the venous plexus situated here, — one of these nerves is especially strong in this place. Before the prostate gland, these nerves are continued in a weak and still finer plexus of organic fibres, which partly lies concealed in the fleshy coats of the pars membranacea urethræ, and in part passes backwards between the prostate and the M. levator ani. This plexus stands also in connexion with branches of the nervus pudendus, within the fleshy coat of the membranous portion of the urethra; but the greatest number of the twigs of this plexus belong to the organic nervous system.

These, then, are continued (divided into many filaments) backwards between the side of the prostate and the levator ani; still hanging together in a plexus and passing upon the side of the bladder, where the fibres are very fine and soft, until they at length reach the plexus hypogastricus, with which they unite.

Close behind the prostate, and by the side of the cervical portion of the bladder, there are, in these plexuses, many ganglions, some longish and some more rounded (ganglia pudenda seu prostatico-vesicalia); to which, also, may be traced some fine filaments from the third or fourth sacral nerves. These ganglions cannot well be considered to belong to the hypogastric plexus, since they are widely separated, and are only connected with it by long and weak filaments. From these ganglions, twigs pass into the neck of the bladder and the prostate gland; but the greater number pass forwards to form the cavernous plexus. The preparation of the nerves in question will be conducted best in the following manner: — first, the cavernous nerves must be sought after upon the root of the penis, in that part where the greater number of them sink into the corpora cavernosa, that is, immediately before and under the symphysis pubis. Some grey nerves may be very soon found before the symphysis, and lying between the dorsal vein and arteries; these are to be followed backwards after the root of the penis has been separated from the pubes, which must then be sawed away —*this must be done very carefully.* When the stems of the cavernous nerves

are arrived at, they must be followed through the fibrous mass which envelops the venous plexus, underneath and behind the symphysis, until they reach the commencement of the prostate, where they begin to subdivide still finer, and form the plexus which has been already described. It will be advantageous to allow the preparation to macerate for some time in spirit, as, by this means, the fine nerves will be more easily distinguished from the surrounding parts. Now, before the most difficult part of the dissection, it will be better to commence the plexus hypogastricus, so that the plexus of the cavernous nerves may be prepared from behind forwards. The preparation of this union is very difficult, and requires the greatest patience; for although the connecting filaments between these two plexuses are numerous, they are very fine and weak.

The nervi cavernosi, consisting of many fine branches, and one large one, will then be found to spring from the plexus cavernosus, which is composed of the roots proceeding from the nervus pudendus on the one hand, and the plexus hypogastricus on the other, and which lies partly between the levator ani and the prostate, and partly in the fleshy coat of the membranous portion of the urethra, but is strongest on the anterior part of the prostate gland. All these stand in connexion with one another, and pass partly under the symphysis ossium pubis, partly immediately before it into the corpora cavernosa; sometimes accompanying the arteria profunda penis, but sometimes through peculiar passages in the fibrous envelope. Some twigs unite with the nervus dorsalis itself, others with the cavernous nerves of the opposite site, and others again with branches of the nervus dorsalis of the other side, and by these means a plexus is formed which accompanies the vasa dorsalia, and from this also twigs proceed, which, penetrating the fibrous coat, range in the corp. cavernosa. Some of the filaments of the plexus cavernosus on the other hand, uniting with twigs of the nervus dorsalis, pass over the corpora cavernosa, and descending into the furrows formed by the two roots of these bodies and the corp. cav. urethræ, are distributed into the last named body.

The nervi dorsales penis are, in distinction to all these nerves, quite white; they pass on the side of the arteriæ dorsalis forwards, and send many, for the most part fine, twigs into the corpora cavernosa. Their anastomosis in the middle line, through communicating branches, occurs generally in such a manner that filaments proceeding from the plexus cavernosus participate in forming it. By far the greatest number of the branches of the nervi dorsales are destined for the glans; a small number only is distributed to the integuments and prepuce. Upon *these* it is that the sensation of the parts depends.

PHOSPHATIC URINARY DEPOSITS, AND THEIR SOLVENT.

To the Editor of the Medical Gazette.

Sir,

In your last number some experiments are quoted, which are entirely opposed to the recent chemical observations contained in the second number of the Guy's Hospital Reports. As my name has been mentioned, I cannot refrain from expressing my firm conviction that your commentator, Mr. Brett, is entirely mistaken in all those points which bear reference to my communication.

The first experiment I shall notice is that by which it is attempted to shew, that muriate of ammonia can lose no portion of base by ebullition. Here your correspondent has been deceived by his experiment; and if he will use, as a test, litmus paper delicately tinged by a weak acid, he will discover his error. Turmeric paper is not sufficiently susceptible for these small operations.

Mr. Brett has stated, that boiling will not produce a precipitation of phosphates, when dissolved in a solution of muriate of ammonia, if any notable proportion of free muriatic acid be present. If Mr. B. will take the trouble to make the solution I have described in the Hospital Reports, he will soon be convinced that he is wrong, for litmus paper is quickly reddened by such a solution, previous to ebullition.

I am at a loss to imagine how Mr. Brett has deceived himself into a belief that the acidity of urine (affording a precipitate of phosphates by heat), is

never increased by boiling. Such an opinion must be held against most obvious facts, though it is certainly necessary to a belief in Mr. B.'s theory of carbonic acid, &c.

It has been somewhat particularly insisted upon by your correspondent, that the solvent action which muriate of ammonia exerts on the earthy phosphates has been long known to chemists: a reference to the Reports will be sufficient to shew that I pretended to no originality on this point, but expressly declared the contrary.

By inserting these few remarks in your next number, you will oblige

Your obedient servant,

GEORGE OWEN REES.

Guy's Hospital,

MEDICAL GAZETTE.

Saturday, April 23, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

IMPORTANT CHANGES IN THE COLLEGE OF PHYSICIANS.

WE have this week to announce the most important step in medical reform which has been taken since the commencement of our editorial vocation. The College of Physicians have abrogated the by-law which required a degree in medicine as preliminary to obtaining admission among their Licentiates! Many have supposed that, in order to become a physician, the degree of M.D. was rendered necessary by some part of the statute under which the College hold their powers; but such is not the case, for when Henry the Eighth originally granted the charter, no restriction of the kind was imposed, and the only stipulation was, that the party licensed should be duly qualified. Of the requisite qualification the College was left to judge, but they, with marvellous self-denial, declined to retain in their own hands the rights thus conferred upon them, and imposed upon themselves voluntary fetters, by compelling all who wished to be admitted either as fellows or licentiates, to come provided with a medical degree. By what, if any, course of study, or by what, if any, extent of qualification, those degrees were to be acquired, the College had no means of regulating, and for a long period do not seem to have paid any attention to points apparently regarded as so unimportant. At length they enacted that two years (!) must have been spent in the study of physic ere the candidate should appear before them, at the end of which time, if the aspirant had purchased a certain piece of parchment at St. Andrew's or Erlangen, he might be admitted a Licentiate of the Royal College of Physicians of London.

It requires no argument to shew that this system was little better than a mockery — one in which a name was substituted for a reality, and a worthless diploma preferred to scientific acquirements. Such, however, is the force of habit, that it was long before the members of the College could be induced to view the question in its proper light; and we are not aware that any formal attempt was made till within the last few years to get rid of a by-law, the operation of which has been to limit the influence and usefulness of the College of Physicians in a very remarkable degree, and which if suffered to continue,—but for another year—would inevitably have swamped it altogether.

One of the great and just complaints against the medical establishments of this country has been, that no one could become a physician without leaving the metropolis to seek his professional education at Oxford or Cambridge, where his opportunities, *quoad*

medicine, were necessarily very inferior; or, if he were not of the Established Church, he had actually to leave England, to seek elsewhere the rank and qualifications refused to him at home. But we mistake: one alternative did remain;—it was open to him to practise a fraud by purchasing a diploma at any of those warehouses for the doctorate which have reflected so much disgrace upon science.

The evil above alluded to was one the existence of which we have often dwelt upon, and the means of remedying which we have repeatedly pointed out. The simplest and most straight-forward method of proceeding we shewed over and over again (see GAZETTE during the last three years *passim*) to be, that the College of Physicians should take the same ground relatively to *their* branch of the profession, which the College of Surgeons held with regard to surgeons, and the Worshipful Society at Blackfriars with regard to apothecaries—namely, that they themselves should regulate the education, and test the qualifications, which they deemed necessary for admission into their body; and that they should then confer upon the party the dignity of their order, by constituting him—a PHYSICIAN.

This, at length, they have done; they have shaken off the incubus which oppressed them; they have broken the fetters which rendered them subservient to every trumpery school in Europe, calling itself a University, and there is now a reasonable prospect of the Royal College of Physicians occupying that prominent place among the professional establishments of the country to which, by their rank and by their charter, not less than by their learning and by their influence, they are entitled, and from which, but for the bigotry of their predecessors, they never needed to have fallen.

We have learnt with satisfaction, that this great measure of reform passed through its legal ordeal of three successive meetings with increasing majorities, and that last Tuesday (April 19) completed the triumph—if we may be allowed to call it so—of liberality over prejudice. Some there are, it is true, who still violently oppose the change; some who cannot endure that education and knowledge should be substituted for matriculation and rolls of parchment. Should these gentlemen ever again obtain an ascendancy in the Councils of the College, and desire to preserve their order untainted, we would venture to suggest the expediency of contracting with some of the German Universities for an annual supply of diplomas; they would thus be spared the pain of seeing others than *doctors* become physicians, and might make a very pretty profit by charging a reasonable per centage for the commission.

As we have stated, the present change consists virtually in the substitution of a curriculum of education under the regulation of the College, in lieu of a diploma, over the pre-requisites of which they have no control. And this leads us to remark that our veracious contemporary* has, with his usual policy, suited his statements, not to the facts, but to the wishes of his party. He represents the object of the College of Physicians to be that of establishing an opposition to the Society of Apothecaries; and then adds, "licenses are henceforth to be sold at both places, if buyers can be found in Pall-Mall East; and the conditions to be complied with preliminary to an examination are made as slender as possible at the new shop, in the hope of catching customers." The answer to this allegation is—that it is utterly untrue: the standard of education required of those hereafter becoming physicians is much higher than it ever has been before, or than

* The *Lancet*, of course.

it is either for the College of Surgeons, or Society of Apothecaries, comprising not less than five years' professional study, including Midwifery and Surgery, as well as three years' Hospital attendance. But we shall publish the curriculum in full, both for the information of our readers, and as giving the lie direct to the servile journalist whose pen has been enlisted against this most liberal measure, and the motives of whose opposition we shall ere long expose.

"Nemo in Permissorum numerum admittatur, qui non prius Præsidentem et Censores certiores fecerit, per literas testimoniales à Comitiis Minoribus approbandas, sese Disciplinæ Medicæ studiis per quinquennium integrum incubuisse.

Disciplinam autem Medicam hæc precipuè studia complecti volumus; scilicet, *Anatomicen*, *Medicinam*, *theoreticam*, *practicam*, *et forensem*, *Chemiam*, *Materiam Medicam*, *Historiam Naturalem*, precipuè *Botanicen*, *Artem Obstetriciam*, et *Chirurgiæ Principia*.

Statuimus insuper et ordinamus, immo hoc summi esse censemus, ut nemo in Permissorum numerum admittatur, qui non priùs sese Medicorum praxi in Nosocomio aliquo idoneo triennium integrum consuevisse, per literas testimoniales Comitiis Minoribus prolatas, comprobaverit.

Nullum vero Nosocomium ad hoc idoneum judicamus quod pauciores quàm centum ægros in cubiculis continere soleat, vel quod non sibi adscitos habeat tàm Medicos quàm Chirurgos.

Si quis autem foris ad medicinam institutus in Permissorum numerum admitti petat, is prius in Comitiis Minoribus solito more comprobet sese non tantum iisdem studiis, quæ nostratibus jam ante injunximus, quinquennium apud suos impendisse, sed et Medicorum praxi intrà Britanniarum fines per annum integrum in Nosocomio aliquo idoneo invigilàsse."

So much for that lie!

But it is not because the circumstance of the members of the College of Physicians throwing open their doors may tend to direct some portion of the current from Blackfriars, that certain parties are so violent against the new arrangement—they apprehend it will interfere with the proposed Metropolitan University, and in this consists the secret of much of the opposition, both within and without the walls of the College. To us it is, and always has been, a matter of indifference by what means the evils in the profession were removed, so that they were *bonâ fide* made to cease. *We* have no personal interests to serve; *we* look for no appointment in the yet unborn University!

We have now for years advocated the simple expedient of the College of Physicians taking upon themselves the duty, as they undoubtedly have the power, of conferring the dignity of "physician" on those whom they find to be fit for that honour. But when, after passing the measure twice, they stultified themselves by throwing it out a year ago, at the third and last time of asking, we declared the decision to be not only suicidal as regarded their own interests, but, in our humble judgment, contrary to the terms of their charter. (See MED. GAZ., April 4, 1835). We turned from them in despair, not unmingled with contempt, and marvelled how so much learning could be associated with such a plentiful lack of worldly wisdom. Our only hope was then centered in the proposed Metropolitan University; and if the arrangements of this had been conducted on liberal and enlightened principles, it might have constituted a noble monument erected over the remains of ancient bigotry and prejudice. But so far as the details have become known, no such liberal views or independent principles are to be expected from it. The number of shareholders in the Joint-Stock Company of Gower Street, who have votes in parliament, is too great for the minister to despise, and — but it is enough to say that the accursed spirit

of jobbing has already tainted the arrangements. A set of names has been handed about as those of the gentlemen likely to constitute the medical examiners. The list may have been imperfect—some names may have been erroneously introduced—but we believe it was put forth as a feeler, and the effect must have convinced the Chancellor of the Exchequer, or rather his confidential adviser, that to give evidence agreeable to the chairman of a parliamentary committee is much easier than to command the confidence of a numerous and enlightened profession. Either from this conviction, or some other cause, the growth of the embryo University has been arrested; and as yet we know not whether the step taken by the College will prevent the birth, or whether it will but hurry on our parturient legislators, and cause the progeny to be

——————— "sent before its time
Into this breathing world, scarce half made up."

We venture, however, to suggest, that as the Minister cannot put a stop to the arrangement above described, nor prevent the emanation of "physicians" from the chartered body already in existence, his best and simplest course would be to come to some arrangement with them on liberal principles, so as to constitute the present College the medical branch of the new University. He would thus confer a great benefit on the profession, avoid the scandal which must attend the sudden appearance of two rival establishments for conferring the highest honours in physic, and though last, perhaps not least, might spare himself a world of vexation and trouble.

On the regulation referred to in the preceding article being passed by the College of Physicians, Dr. Elliotson desired that his name might be withdrawn from the list of the Council, a proceeding which, coupled with various other circumstances, we regard as abundantly significant. The Fellows, of whom there was a very full meeting, not only at once accepted the resignation, but prevented the possibility of its being retracted, by immediately electing Dr. Southey in his place.

MECHANICAL PHILOSOPHY AS APPLIED TO MEDICINE.

Abstract of Lecture Fourth: as delivered at the Aldersgate School,

By Dr. Birkbeck.

Dr. Birkbeck commenced by stating, that upon this globe, surrounding it on every side, and extending far above the most lofty mountains, elastic matter, exercising an important influence upon bodies immersed in it, is found. The existence of this elastic matter, in consequence of its being quite invisible—for it is not even dimly seen—was, during a long period, very imperfectly recognized. It was certainly noticed by the earliest philosophers—Hero, Ctesibius, and others; but it could not be said to be understood, until Toricelli pursuing the researches of his illustrious master, Galileo, in the year sixteen hundred and forty-three, discovered the weight and consequent pressure of the atmosphere. Subsequent experiments have rendered the investigation complete; and its mechanical history is now, it may be asserted, well understood. Yet, even at this day, when the actual weight of the air which rests upon the human body is stated, some degree of incredulity as to its extent prevails: we are scarcely prepared, without very cautious inquiry, to admit that we at all times sustain a load varying from thirteen tons to fourteen tons and a half. This, however, was shown to be the case by the following calculation. The weight of the air resting upon one square inch of surface, as would afterwards be proved, was taken at fifteen pounds; upon a square foot, it would therefore be 2160 pounds. The superficies of the adult human body being about fifteen square feet, the number of pounds multiplied by this quantity (2160×15) will give for the whole pressure thirty-two thousand four hundred pounds, or fourteen tons and a half, nearly. Adopting the same method of calculation, Professor Cotes determined that the weight of the entire atmosphere was equal to that of a globe of lead sixty miles in diameter.

That we are unconscious of this vast pressure, it was said, arises from our having been subject to it from the moment of

our birth, and from the perfect equality of the pressure. When we move quickly against the air, or when it is moved quickly against us, we become sufficiently aware of its material nature by its resistance. We witness its power, likewise, in those violent movements of seventy, eighty, or one hundred miles an hour, when, as a storm, or hurricane, it overturns, and sometimes destroys, large buildings or other obstructions to its progress. The effect of its weight may at once be demonstrated by disturbing the equality: thus a tall glass vessel, moving ordinarily with freedom, was rendered immoveable on the plate of the air-pump; the hand was firmly fixed on the top of an open receiver, and a membrane, not very strong, stretched tightly over an open vessel, was, by the same contrivance for depriving one surface of support, first made hollow, and then torn in pieces. Other experiments were exhibited, especially the Magdeburgh hemispheres, to establish the weight of the atmosphere; and afterwards its elasticity, the other important mechanical property, was similarly established. The height of an atmosphere of equal density, 27·818 feet, or five miles and a quarter, was then mentioned, and the indefinite extent of an investing fluid, decreasing in density as the elevation increases, with the actually measured gradations detailed, was demonstrated.

Dr. Birkbeck next proceeded to apply the principles of pneumatics to the explanation of several phenomena connected with animal systems, and especially with the human body. He again noticed the cranium, as affording a cavity impervious to the air, and accounted, by its pressure, for the head not being emptied of blood on decapitation; and for the fact stated by Dr. Kellie, as to the full quantity of blood appearing to occupy the vessels of the brain, when all the rest of the animal (which had been destroyed by bleeding) was quite bleached. Dr. Kellie, indeed, declares that more blood than natural remained there; which certainly could not have been the case. He then noticed the effect of the air-tight parietes of the chest, in regard to the contact of the pleura pulmonalis and pleura costalis, and of the elasticity of the lungs in resisting their expansion; as well as of the open elastic tube, the trachea, and its numerous ramifications. Thus the processes of inspiration and expiration were connected with the doctrines before established, both as regards the mechanical and pneumatic influences inducing the process of respiration. The power of the air to follow the minute ramifications of the air-tubes, in consequence of its weight and elasticity, was insisted upon; and the effect of the current augmented by resistance at the closed glottis, in expelling extraneous matter, such as mucus, pus, &c. was described. The purpose of respiration was shown to be far more important, than any simple result from the alternate introduction and expulsion of an unchangeable aeriform fluid; and the actual result was briefly detailed. That a surface of very great extent is provided for the accomplishment of the very important mutual action of atmospheric air and blood, within the lungs—an extent nearly thirty times that of the whole external surface—was rendered probable by the following calculation, derived from Monro *secundus*. The air-vesicles being only one-eightieth of an inch in diameter, there will be 512·000 of them in one cubic inch. Let the cells be supposed cubical; the sides will then amount, in a cubic inch, to 3·072·000: from this number deduct one-third for apertures of communication, and more than two millions of membranes will remain, constituting a space equal to three hundred and twelve square inches, or upwards of two square feet. But as the lungs in a full inspiration contain about two hundred and twenty cubical inches of air, the whole internal surface exposed to the air will be four hundred and forty feet (220×2), or nearly thirty times greater than the whole external surface, already stated to be about fifteen square feet.

Notice was next taken of the effect of atmospheric pressure in preserving the head of the thigh-bone in contact with the surface upon which it rolls; and of the difficulty which has sometimes been experienced in separating them: resembling the difficulty felt by glass-grinders and opticians, in regard to large lenses and the tools in which they are formed The assistance derived by the lacerta gecko and the leech, in progression, as well as by the house-fly, the dytiscus marginalis, and other insects provided with an extensive and beautiful pneumatic apparatus, was spoken of. The aid obtained from such pressure in fixing the remora, the sæpia, and the univalves, was also noticed; as well as the assistance derived by all the insects termed suctores, from the same source. Other applications of the same principle, equally interesting, if time had been allowed, would likewise have been investigated.

And now, said Dr. Birkbeck, I have done. I regret exceedingly that I have not had an opportunity to do more justice to the subject, and to my desire to assist, by the delivery of a few scientific lectures, my friends, the able and intelligent teachers of this rapidly advancing establishment: my health and strength, however, have not allowed me to do more for them and for

you; but I hope, that, on some future occasion, I may enter more minutely into this important inquiry. Enough, I trust, has been accomplished, to establish the importance of mechanical philosophy, when conjoined with human physiology, and to show that the splendid and mysterious effects resulting from the agency of the living principle, suffer no disparagement from an association with the more humble and intelligible inductions from material phenomena. I have placed you, I am aware, upon the mere threshold of the science to which I have directed your attention; and I therefore entreat you to consider yourselves hereafter, in regard to this department, and, indeed, in respect to the departments which have here been extensively and profoundly investigated, as entering upon the most valuable and important part of your studies. You will now refer, without your guides, to the great book of nature; in which you will find an exhaustible supply of objects and phenomena, the most varied, beautiful, and magnificent. It will prove an occupation always refreshing and delightful: and as you thus proceed in acquiring fresh accessions of real knowledge, you will find that it may be said of knowledge, as it was long ago beautifully and emphatically said of virtue, that "all her ways are ways of pleasantness, and all her paths are peace."

THE MEDICO-CHIRURGICAL REVIEW AND MR. ASTON KEY.

Letter from Mr. H. J. Johnson.

To the Editor of the Medical Gazette.

I have read, sir, with much surprise, a letter from Mr. Aston Key, in the last number of the Medical Gazette. Its title is "On the Agency of Iodine in Ulceration." It might, with more propriety, have been designated "Some Conjectures on the Agency of Iodine in Ulceration, and Elaborate Abuse of the Messrs. Johnson." I say, sir, of the Messrs. Johnson, for such is the somewhat slang designation applied no less than thirteen times to my father and myself. But although the "Messrs. Johnson" are thus ostentatiously insulted, the personalities of Mr. Key are substantially levelled at me.

The letter of this gentleman is of such a character that his best friends must deplore the passion that appears to have given it birth. I will not stoop to imitate its tone, nor to retort on Mr. Key the injurious epithets and unwarrantable imputation which he so lavishly bestows on me. I am, as he asserts, an attaché to a school in the "far West;" and I hope that, as a lecturer, I shall maintain the character of which the pupils of that school are proud,—of not forgetting the manners of a gentleman. How far and how well Mr. Key represents the feelings and the bearing of a school in the "far" East, must be left to others to determine. He taxes me with volubility: I yield the palm to him in that. His proximity to a celebrated market may possibly account for its peculiar characteristics.

The cause of Mr. Key's complaints must be sought in two critiques on two papers of that gentleman. The papers in question were published in the Medico-Chirurgical Transactions, and the critiques appeared in two separate numbers of the Medico-Chirurgical Review, of which Dr. Johnson and myself are editors. I cannot admit that the conductors of a journal should be saddled with the authorship of every article and of every obnoxious expression contained in it: but, in the present instance, I am willing to take my full share of responsibility for the criticisms to which I have alluded, and to incur whatever censure may fairly attach to the reviewer.

Mr. Key has obscured the issue between us by a thick stratum of abuse. When that is shovelled off, the question itself is simply this:—

Mr. Key's papers in the Medico-Chirurgical Transactions were essentially directed to two objects—to prove that there is a wider distinction than is supposed between ulceration and absorption, and to revive the antiquated notion that suppuration is a sort of resolution of the tissues. These were the principal objects of his papers; and, to establish these, he industriously laboured with the usual machinery of facts, and reasonings, and illustrations. The critiques were, as I stated, two in number; one long, and both of an elaborate, or, at all events, of a circumstantial description. If they had been characterized by disingenuousness or partiality—if decency or justice had been violated—the obvious and the proper mode of exposing the reviewer would be that of bringing forward the specific instances, and proving, by the laws of evidence and reason, the offences charged against him. By their award I should willingly abide; and I am perfectly content to refer those who may feel an interest in the present controversy, to Mr. Key's papers and to the criticisms on them, and to beg the reader to form a dispassionate judgment for himself.

But Mr. Key has not proceeded in this rational and customary manner. To establish the injustice of two long critiques, on two involved hypotheses, he selects an

incidental illustration of his notions—itself a matter of opinion; and, opposing his *ipse dixit* to the reviewer's, he arrogates the exclusive property of observation, experience, knowledge, and truth, and pelts me with a handful of foul names.

The matter of opinion is the agency of iodine. Mr. Key asserts that it is a powerful tonic. "Iodine," he says, "when used properly, is a powerful stimulant and tonic; it excites the pulse, and increases its volume; it stimulates the stomach, increases the appetite, and fattens the patient; it gives tone to the extreme vessels and nerves of an ulcer, and prevents the inflamed texture being destroyed by ulceration."

Entertaining these opinions, now, for the first time, explicitly avowed, Mr. Key had previously remarked, in his last paper, "It is difficult to explain or to reconcile the action of some remedies, with the supposition of absorption being concerned in ulceration. One of the most powerful remedies that we possess, and that exerts a remarkable control over the ulcerative process, is iodine. The most active phagedænic ulcers, that threaten the destruction of parts, are often found to yield, in a surprising manner, to the influence of this medicine, and to put on a healthy granulating appearance: and yet iodine is thought to act powerfully in increasing the action of the absorbents; tumors of considerable size often yielding to its action, and being absorbed. How is it that, in the healing of an ulcer, it checks and puts a stop to the absorbing process, and, in the case of a tumor, quickens the action of the absorbents and gets rid of the mass? Here are two actions of a remedy opposed to each other, and inexplicable, so long as ulceration is regarded in the light of absorption."

Mr. Key, in the passage I have quoted last, [the passage contained in his original paper], cited the action of iodine as confirmatory of his hypothesis that ulceration and absorption differ. The argument stands thus:—Iodine is thought to promote absorption; but iodine checks ulceration; therefore, ulceration is not absorption. You must observe, sir, that the whole force of the argument rests on iodine producing absorption. If iodine be really a stimulant and tonic, if it actually fattens those who take it, it does not support the theory of Mr. Key, because stimulants, and tonics, and fattening things, are well known to tend towards checking ulceration and absorption. Mr. Key said nothing of the tonic qualities of iodine in his paper. He is now on the horns of this dilemma;—either his argument drawn from the action of iodine was inapplicable; or, believing the general notion of that action to be erroneous, he still made use of it to support his case. I allude to this logical inconsistency *en passant*. It does not bear immediately on the present issue, but it forms a very apposite example of the general style of reasoning of Mr. Key.

The question now between us with respect to iodine arises from a criticism on the passage I have quoted. Let me again introduce it to your notice.

"If Mr. Key could prove that iodine was a great promoter of absorption, and at the same time one of the most efficient agents in checking rapid ulcerative action, we should admit that there was plausibility in this argument. But we differ, *toto cœlo*, from Mr. Key, in his very premises. We deny that iodine is an efficient remedy in cases of phagedænic ulceration. Nay, we will go farther, and affirm, as a general fact, that iodine is one of the very worst remedies that could be administered in phagedæna. Our readers must observe, that phagedænic ulceration may occur in circumstances diametrically opposite,—in a state of system requiring depletion, and in a state of depression and extreme irritability. The former, so far as we have seen, is the exception; the latter the rule. It is possible that in the former, iodine may now and then be beneficial: we are certain that in the latter, opium, the volatile alkali, stimuli, are the remedies to which the surgeon must trust. These are the remedies that build up, rather than pull down; and as reason suggests their use, experience justifies it. On this point we can speak with the positiveness of careful and extensive observation; and here, on the premises of the argument, we are opposed to our author."

I admit that these opinions were uttered in too free, and too *brusque* a manner. I regret that in this instance (I hope the only one) I have placed myself on a level with Mr. Key, and I make him a present of all the advantage he may reasonably claim from this candid admission.

I must own that, for a stimulant and tonic, I have seen iodine produce rather curious consequences*. It has often been my fortune to see people *not* fatten on it. On the contrary, they have frequently grown sallow and emaciated, and presented those symptoms of a nervous character, which rendered it necessary to

* I have presumed throughout that Mr. Key has been speaking of iodine, and not of the hydriodate of potass. The action of the two is in some respects dissimilar. Were a man to affirm that he found potass an useful purgative, and afterwards explain that he alluded to the sulphate of potassa, we should be apt to think that the current of his ideas was disturbed and muddy. Of course, then, the remarks of Mr. Key apply to the iodine itself.

withdraw the medicine. If, as a tonic, it occasions absorption of a bronchocele, or of those specific morbid growths on which it occasionally exerts such remarkable powers, I can only say, that it differs materially from other tonics and other stimulants. If, as a tonic, Mr. Key usually prescribes it, his patients may exclaim to him, as Cromwell did to Sir Harry Vane—"Oh, Sir Harry Vane, Sir Harry Vane! the Lord deliver me from Sir Harry Vane!"

The question of the virtues and the agency of iodine is one which no argument can settle. It is essentially a question of individual opinion—of opinion founded, indeed, upon facts, but not the less of opinion. If the sentiments, on this subject, of any twelve of the most experienced surgeons and physicians of London were collected at this moment, and compared, I am sure they would be found to differ widely. There is scarcely a matter connected with the administration of remedies, on which the discrepancies of practical men are so striking. Is it decent, then, in Mr. Key, in the midst of this uncertainty, to set up his opinions as the standard of right—his hospital practice as the bar for arraigning the practice and the information of others? He erects Mr. Cock as an arbiter. With the utmost deference both for Mr. Cock and Mr. Key, I cannot implicitly bow to their authority. I may be wrong in my opinion that iodine is not a valuable remedy for phagedæna, attended with depression and extreme irritability; I *was* wrong in expressing that opinion so positively; but, right or wrong, Mr. Key is not justified in addressing to me the language that he does, and in stigmatising an opponent on a dubious question as an ignoramus and a fool. If this be the scientific lesson that he reads his class, assuredly it is not what I teach mine: a truculent logic, more debasing to its advocates than injurious to those against whom it is pointed.

But the controversy on iodine forms but the half of Mr. Key's letter; the other half is devoted to unmitigated abuse of me. His accusations are of rather an extraordinary character.

According to this gentleman I am an inexperienced youth, too infantile to have done with nursery books, or to have shaken off the horror of nursery tales. Thirty years usually do more than that; and I possess sufficient vanity to suppose myself not far behind the level of my age. Youth is a fault that time will remedy; but it is not so certain that years will exert the same salutary influence on the intemperance of Mr. Key. There is a proverb on this subject which I will not quote. The passions of youth are extenuated by its generosity; but violence in age is a ludicrous as well as a painful spectacle. It is like flat champagne; the aroma and the sparkle have departed, whilst the pinching and injurious qualities remain.

The second accusation is as judicious and conclusive as the first. I present it in the words of Mr. Key:—

"Where this young gentleman has passed his time since the period of his pupillage is not easy to divine; certainly not in a metropolitan hospital, for there can scarcely be one that does not, like Guy's, afford abundant evidence to give a direct negative to his assertion; he is, indeed, far behind the practical knowledge of his own times. It may be that he passes his time in the recess of his closet, learning the art, or the mystery, of reviewing. Practical surgery is one thing, reviewing another. Let me assure him that the latter is a bad school for learning his profession practically, or even for acquiring liberality of feeling. I speak not from personal experience in reviewing, as I never wrote a review; but I judge, as in the present instance, from the fruits of those who do."

One thing is quite certain. I have not passed my time in a school where vituperation is held to be argument. What my professional knowledge may be, it does not become me to say. I am sure that Mr. Key is a very inadequate judge of it; and I hope that his inference as to my ignorance is as erroneous as his supposition respecting my pursuits. I can well believe that he never did write a review, for I am conscious that reviewing has *not* produced in me that peculiar species of liberality of feeling so evident in him.

If the preceding accusations are extraordinary, that which follows is more so. Mr. Key denounces me as a thick-and-thin panegyrist of Sir Benjamin Brodie, and a systematic literary ruffian. This serious charge is diffused through six columns of close letter-press, and almost every paragraph ends, like the ballad of "Down derry down," with a chorus of the name of Sir Benjamin Brodie. I scarcely know whether to laugh, or to feel indignant, at the passage I shall quote—to laugh at its absurdity, or to feel indignant at its groundless virulence.

"You must know," says Mr. Key, in the words of some real or fictitious friend, "that one of the Messrs. Johnson is a candidate in future for the honours of the profession, and is an *attaché* in some shape to a school lately established in the far West. To both these objects he makes his review subservient, and for both he wishes to have the assistance and support of Sir Benjamin Brodie. You will observe that in all his reviews he is careful,

most careful, to drop nothing from his pen at all likely to annoy that eminent surgeon, but seizes every opportunity of applauding, *un peu fort*, it may be, whatever comes from his pen or from his lips, and of victimizing all who are guilty of *lèse majesté*. You are guilty, and will make a good subject to offer up at his shrine; depend upon it you will be broken upon the wheel,—quietly enough, perhaps, for they will take care to stifle your cries; but your fate is decided. Your *disjecta membra* will then be offered up as a sacrifice; or perhaps you will be smothered *en masse* (doubtless prophetic of the screw press), and afterwards offered as a holocaust on the reviewer's altar of adulation."

Upon my honour, sir, I am almost inclined to feel horror-struck at discovering my own bloody-mindedness. I am much in the situation of some well-meaning man, who, having never to his knowledge committed any particular atrocity, is told by some eminent professor of phrenology that he possesses an enormous bump of destructiveness, and that he *must* be a murderer; or, rather, I am like the *bourgeois gentilhomme*, who had talked prose all his life, and never knew it.

It is true that I was educated at St. George's Hospital—it is true that I am a lecturer on anatomy in Kinnerton-Street—it is true that I enjoyed, what I am not ashamed nor afraid to avow as a very great advantage, the opportunity of long observing the practice, and hearing the opinions, of Sir Benjamin Brodie; but it is not true that I prostitute the journal I conduct to the vile purposes of private intrigue, or of personal aggrandizement; it is not true that I devote myself to the systematic adulation of Sir Benjamin Brodie, or to the immolation of all who may become his scientific opponents. To this unwarrantable imputation I can give but one reply—a direct denial. An imputation monstrous and improbable in itself—advanced without even the semblance of proof—urged in passion—and born in disappointment.

Ill-natured persons have not failed to remark, that the charge of profiting by patronage proceeds with a bad grace from Mr. Key. He has himself smarted under the unpleasant and unjust aspersion of participating in the benefits of nepotism—a term applied, I understand, on the occasion. The consciousness of unmerited obloquy should have made him pause before he heaped it on another's head.

Mr. Key commits a material error when he states that I sneered at the salutary efforts of nature. He does not suspect, what your readers may, that the sneer, if such there was, might possibly not be directed at the doctrine, but at an improper and absurd application of it. The theory of the Vis Medicatrix Naturæ, when pushed to the extreme, defeats its own object; and nature must blush to find herself sunk to a cobbling mechanic, patching up one hole, and making a worse.

I quite coincide with Mr. Key in his truism, that "no human being can injure or debase the mind of another; this lies only in his own power; by himself only can man be thus injured." This reflection renders me perfectly contented under the calumnious imputations which he pours upon me; and I cannot but feel how singularly his practice tallies with his text. I know that he cannot injure me, but I see that he materially degrades himself.

I would fain believe, indeed I do, that Mr. Key's surgical talents are superior to his wit. If brevity be, as is said, its soul, and intelligibility its head, the acephalous monster which proceeds from Mr. Key possesses no sort of animation. His statements and his jokes upon the sieve and screw, remind me, in some measure, of what Sheridan said of the first Lord Dundas. "His Lordship possesses, in an eminent degree, the gifts of invention and memory, but he employs those qualities as no one else would do; for when he states his facts, we admire the force of his invention, and when he utters his jokes, the powers of his memory."

Mr. Key concludes by observing, that it is necessary to make no apology to the Messrs. Johnson. Mr. Key must pardon me. I will not say that he betrays an imperfect acquaintance with the customs of society, but I will say, that when sordid and disgraceful motives have been attributed by one gentleman to another, an apology is usually considered due. From Mr. Key, however, I require none. With feelings of personal indifference, I began this letter; and with feelings of indifference I end it. I hope its moderation may contrast with the violence of Mr. Key's.

It would not be difficult to retort on him severely; for looseness of reasoning, and blindness of passion, expose him on every side to sharp recrimination. But the unenviable situation in which he has placed himself, reads me the best lesson of forbearance. The Spartans, to disgust their children with drunkenness, exhibited a Helot, drunk.

As this is the first time I ever had occasion to meet Mr. Key in public, it will not be my fault if it is not the last. No consideration shall induce me to re-engage in the present controversy.

I remain, sir,

Your obedient servant,

HENRY JAMES JOHNSON.

8, Suffolk-place, April 19, 1836.

INJUSTICE AND ABSURDITY

OF

THE MEDICAL PROVISIONS OF THE PRESENT POOR-LAW.

To the Editor of the Medical Gazette.

Sir,

I take the liberty of forwarding the inclosed for insertion in your widely-circulated journal, and have merely to observe, for the present, that, at a meeting of medical gentlemen in our neighbourhood (upon the occasion of an interview with the Deputy Commissioner appointed to settle the medical portion of the new Poor Bill), Mr. Power did not even attempt a reply to the arguments adduced by myself against it; at the same time due credit must be given to that gentleman for his urbanity and politeness in hearing our opinions. The inclosed was written in haste, in the few minutes that I could spare from professional duties.

I am, sir,
Your most obedient servant,
D. R. M'Nab, M.R.C.S.

Epping, April 18, 1836.

To Alfred Power, Esq., Deputy Commissioner of the Poor-Law, and to the Guardians of the Essex Unions.

Gentlemen,

The scheme for medical assistance and relief, which you have suggested in all the unions of this county, and, by the conduct of some nameless practitioners, have been enabled partially to adopt in this, claims the dispassionate attention and consideration of all the established practitioners both of this neighbourhood, and of the kingdom at large.

That the scheme is impracticable and unjust, I will endeavour respectfully to shew to you; and that it is absurd and odious to all respectable and conscientious men, is almost too self-evident to need either proof or illustration: and first, with regard to its impracticability.

You may contract for meat, for bread, for flour, or clothing, at per head, and the test of the senses will afford a sufficient guarantee and security against imposition; but to contract, in like manner, for a medical man's industry, judgment, and experience, and the application of those talents to any given purpose of utility, is visionary and absurd: and, independent of the mysterious dose which a pauper or a *free* patient may swallow under the various forms of pill or potion, I contend that both the one and the other are equally out of your power either to estimate or control. And let the amount of your assessment for the purpose of remuneration be what it may upon the independent labourer, (as he is delusively called in schedule B) the principle is equally inapplicable to him, as it is unjust to the pauper in schedule A; and to the former still more so, as it obliges him, in many instances, to employ some district parish-surgeon, in whom, perhaps, he has no confidence, and against whom he has no veto during the period of the contract. I will now add a few words to illustrate the injustice and absurdity of the measure, for both are very nearly allied. First,

It is unjust to lay a poll-tax of 2*s*. or 2*s*. 6*d*. per head for adults, and 6*d*. for children, upon any class of the community, under the frivolous dread of "a doctor's bill:" and it is still more so, when the pretext is mainly intended to throw the burthen from the shoulders of the parish on the backs of the lowest, and, in my opinion, the most oppressed portion of this neighbourhood, viz. the agricultural peasant—and this, too, under the fictitious plea of rendering him independent of the parish. This, I venture to assert, is the true state of the case; and this, moreover, is the view which the generality of the peasantry will take of it, when they come to reflect, notwithstanding the urgent expostulations of sundry Guardians, who, under your pupilage, have taken a different view of the question.

Where, I would ask, is the *man* or *family* in this county, that has been pauperized either by the enormity or exaction of a "doctor's bill?" for I apprehend, by the first report of the Poor-law Commissioners, that this is the main, and almost only argument, in favour of the adoption of the measure. Secondly,

It is unjust towards the medical practitioner who engages for the attendance, in schedule A, on destitute, infirm, and dependent paupers, to oblige him to attend on similar pauper terms, and under a similar base contract, a certain number of those you wish to style independent labourers, from whose united subscriptions he may provide an adequate remuneration for his public services; to force him thus to rob his private connexion to ease the parochial burthens, which he must do, if the neighbourhood abounds in labourers, as in many *they* form two-thirds, in some three-fourths of the whole population, viz. at Matching, Magdalen Laver, Nettswell, Parndon, &c.; at any rate, it is unjust to place him in a situation, by the veto you enforce, of rendering himself obnoxious to many, and, in the end, to bring his professional conduct into general suspicion and universal disapprobation.

As farmers are much interested in this question, and form a great proportion of the Board of Guardians, I will, in legal phraseology, endeavour to illustrate the whole, by an "hypothetical case in point." A farmer takes a large farm, with the addition of many acres of land of inferior quality: having cultivated this for many years to the best of his power, and to the satisfaction of the landlord, or lord of the manor, he is suddenly told by the all *powerful* man, that he shall expect him hereafter to continue the cultivation of the common land with equal assiduity and attention; but, in lieu of the produce, he shall allow him a certain sum per acre, more or less, according to the number of acres. I will now ask the following questions:—

1. What zeal or industry should you be likely to exercise on that land, on such terms?
2. Would you consider the proposal just?
3. Would you take any pains or trouble to cultivate it at all, for so unjust a man?

In this predicament will the practitioner be placed, who undertakes the medical superintendence of parish clubs, and paupers.

I have now, sir, endeavoured, however imperfectly, to point out the gross injustice to the poor man, and the flagrant imposition to the medical man: let me next draw your attention to its egregious absurdity.

I can scarcely conceive any scheme better calculated to attract the attention and cupidity of the unprincipled quack (and here let me be clearly understood, I do not refer to the advertising mountebank, but to the still more mischievous, inasmuch as it is concealed, quackery which abounds in the medical, as well as in all other professions); and whether the lives of your schedule A, and schedule B, are intrusted to the *merciful* consideration of "bread pills," or "mocked by a julep," under a puerile system of the "medicine expectante," or are exposed to the merciless ravages of "incipient evacuations," or of "drastic poisons in exaggerated doses," the result will be the same—viz. to make your proposed plan *pay* the unprincipled candidate; and I can affirm, without contradiction, that to him only *can* such a plan be made an adequate remuneration. You can, I think, only escape one of these extremes by the adoption, in your next advertisement for candidates, of the homœopathic system of infinitessimal doses, the whole of whose materia medica may be comprehended in the limits of a snuff-box—men who have not only simplified remedies, but diseases also, by referring them to one common origin.

I shall for the present, gentlemen, close these observations, with the assurance that I do not accuse you of *intentional* injustice, either to the poor man or medical practitioner; but that in your zeal for the execution of your official duties, in carrying forward the principle of the new poor-law, you have stumbled upon a practical error, in its very nature contrary to the principle of independence, in that truly useful and beneficial legislative enactment. I therefore implore you to pause ere you proceed too far with a measure which will, I fear, tend much to destroy every good feeling of humanity which has heretofore distinguished the profession to a very extensive degree, and to weaken the ties of benevolence which have existed between the medical man and the lower classes of the community, by a compulsory contract, which, in the end, will prove hateful and obnoxious to all, and troublesome even to yourselves. I therefore, most respectfully, for the present, take my leave, and have the honour of remaining, gentlemen,

Yours, &c.
D. R. M'Nab, M.R.C.S.

Epping, Essex,
April 18, 1836.

EXTRACTS
FROM
DUTCH AND GERMAN JOURNALS.

HÆMATURIA.

In the *Pract. Tijdschrift*, 1835 (July—August), Dr. Egeling, of Barlem, relates the result of two cases of hæmaturia, in which he has found the balsam of copaiba to be of essential service.

The first was that of a man who had suffered under hæmaturia for some time, and in which the ordinary remedies failed, but which quickly disappeared under the exhibition of the bals. copaibæ.

The second is that of a woman who had suffered under catarrhus vesicæ for many years. She could not retain her urine for any length of time, and in every discharge of it a copious viscid and purulent mucus was precipitated to the bottom of the vessel.

The uva ursi was first tried, and appeared to do good, as the discharge was somewhat lessened in quantity.

Suddenly, however, and without any explicable cause, there was a discharge of blood with the urine, which probably came from the bladder, although it may possibly have originated in the kidneys. The muco-purulent discharge returned now as violently as ever; every day there was a thick deposit of this excretion, covered

with a layer of blood. All usual remedies were applied during the space of some weeks, but without effect; but now the balsam of copaiba, administered at first in one-drachm doses, produced a perceptible improvement in the colour of the urine, and a lessening of the discharge of mucus and blood; and after the dose had been increased to two drachms, there was no trace of blood, and the other excretions were reduced to a small quantity.

Although the observations could not be continued farther, there has been at least no repetition of the sanguineous discharge.

NUX VOMICA IN PROLAPSUS ANI.

Dr. Schwarz, of Hesse, in Brunswick, recommends nux vomica as a specific in this disease. He has used it as such, with the best effects, during ten years, during which time he has administered it both to children and adults, and has found it efficacious in cases which had not only become severe from their duration, but also through neglect.

One case quoted is the following:—

Four years since, a workman, aged 18 years, had been suffering during the previous three years from prolapsus ani, in consequence of a severe diarrhœa. The rectum was at that time so relaxed, that it descended with every effort, and could only with trouble be held back so long, till another effort caused its reprotrusion. After the patient had taken the nux vomica for fourteen days, accompanied with proper diet, the rectum descended less often.

The medicine was then given in combination with some grains of ext. rhatanæ, and after it had been persevered in for some weeks, the prolapsus was removed.

In the case of little children, Dr. S. usually employs a solution of the extract in distilled water, in the proportion of 1 to 2 grains in ℥ij. of water; and of this solution 6 to 10 drops are administered every four hours. Usually the prolapsus is removed by the following day.

In the case of older children, Dr. S. recommends an appropriate diet to be ordered. The dose may also be increased to fifteen drops; and to ensure the perfect removal of the disease, the doses should be repeated twice a-day for a week after the rectum has ceased to descend. In the case of suckling infants, two or three drops is the dose. When there is any unusual degree of obstinacy, Dr. S. (as in the case above related) combines the nux vomica with extr. rhatanæ.

HUMAN RUMINATION.

Dr. Zeppenfeld, of Bockum, relates his having observed distinct rumination in the case of a man, now 60 years old, and his son, aged 28. They have both been addicted to it from their childhood.

The food is thrown up three or four hours after a meal in distinct balls, with uninterrupted and easy impulse, into the mouth; at first it has no unpleasant taste, but shortly before the cessation of the process it becomes rather sour. Both persons are in the enjoyment of good health, and the remainder of the family is free from this ox-like peculiarity.

SALIVATION IN PREGNANCY.

In the *Wochenscrift für die gessammte Heilkunde; Berlin:* for 18th Sept. 1835, are recorded two very decided instances of irritation in the salivary glands depending upon pregnancy. The first is by Dr. Hamm, in which case the woman had suffered a repetition of this unpleasant condition throughout ten pregnancies; it was so severe as to cause great exhaustion, and at times faintings. The teeth and gums presented the usual appearances of a person under the effect of mercury.

The other case was observed by Professor Casper, who, as well as other physicians, tried all suggested means to lessen it, but without effect. In this instance it existed through five periods of pregnancy, and was so constant and early in its occurrence, that the patient considered it as the first actual proof of her condition; and as regularly as it occurred, so regularly did it cease immediately after delivery.

FISTULA OF THE ALIMENTARY CANAL.

In the same journal for the 5th February, 1836, are related two cases of fistula of the alimentary canal, healed by the actual cautery, from contributions from his case-book, by Dr. Fingerhuth, of Esch.

Case I.—A robust labourer, aged 24 years, fell backwards while he was carrying a heavy stone in both hands. By this means he suffered a severe contusion in the right lateral region of the abdomen, from seven to eight inches in circumference. Immediately followed nausea, repeated vomiting of a bitter fluid, and pain in the injured part, which extended as far as the right shoulder. Dryness of the mouth and urgent thirst excited the patient to drink, which he had no sooner done than the fluid was again thrown off. Costiveness lasted for many days, and the urine passed was small in quantity and at first seldom ejected.

Cold fomentations and clysters had, indeed, lessened these symptoms, but were nevertheless insufficient to prevent the formation of several abscesses. After a lapse of six weeks, one of these opened spontaneously, and discharged a quantity of bloody pus, mixed with feculent matter.

Hitherto the patient had been without medical advice, during seven weeks in summer; but being alarmed by the existing state of things, he requested my attendance.

I found him much emaciated; the abdomen (especially on the right side) distended, tense, and having a fistula situated on the same side, of about four to five lines in diameter, somewhat lower than the navel, and about two inches distant from it: from it were discharged an ichorous pus and fluid fæces. Above this fistula, and corresponding with the lower and anterior margin of the liver, was a swelling, somewhat pointed and redder, which evidently fluctuated. An incision into this liberated a tolerable quantity of pus, resembling wine-dregs; upon this the parietes collapsed, and the patient was freed from the violent pain he had before experienced, and was enabled to lie on his right side much better than heretofore. Under the continuance of warm emollient cataplasms, a continual internal treatment, and the exhibition of a mild nourishing diet, the abscess of the liver soon healed, but the fistula opening into the intestine continued undiminished, and still allowed the fæces to pass freely through it. This unpleasant state of things was somewhat diminished by the application of a bandage and compress; but the shifting of the bandage, and the irritation caused by the discharged fluid, with which the pad was saturated, acting on the surrounding parts, added to the loathsomeness of such a consideration, rendered it the increasing wish of the patient that something should be done to rid him of his lasting and annoying misfortune.

The first plan which suggested itself, was to destroy the mucous surface of the fistula, and endeavour to change it into a granulating border: to this end I tried many applications, but without success. Amongst them, I found the tinct. cantharid. applied on pads of charpie, the most effectual. However, even these granulations were weak and pale, and they remained so, although I ordered warm stimulating cataplasms, in order to promote its effect. Stimulating unguents, which I ordered during a fortnight, with the same object, had as little effect. Although the fistula was a little lessened by these weak granulations, it still showed no inclination to close. I now determined to apply the actual cautery, which I did on the following day, in this manner:—A cylindrical iron, exactly corresponding with the diameter of the fistula, was heated to a little below the red heat, and then introduced within the fistula; by which means the whole of the lining membrane was cauterised; during this, the patient complained of severe pain. Abundant granulations soon covered the cauterised part, which lessened itself rapidly, and the fistula was finally entirely healed, after having been touched once more with an iron not larger than a crow-quill.

Case II.—A strong lusty ploughman received, in the summer of 1834, a kick from a horse, in the abdomen, on the right side, about two inches above Poupart's ligament, and equally distant from the anterior sup. spinous process of the ilium and the linea alba.

Two days after the accident the patient was placed under my care. I found him suffering under a decided inflammation of the alimentary canal, with the usual characteristics—countenance pale, tongue red and dry, insatiable thirst, after every attempt to quench it; followed by a vomiting of a greenish, bitter fluid, great uneasiness, the abdomen tumid and painful, but still the place where the injury had been received was only marked by two small ecchymoses. A decided antiphlogistic treatment lessened all the most urgent symptoms, but could not prevent the formation of pus. Twenty days later, two abscesses opened themselves at the distance of an inch from each other, and discharged purulent matter and fæces; this proved, upon examination, to be in connexion with the small intestine. The treatment pursued in this case was the same as in the former; and here, also, after the tinct. cantharid. had lessened the diameter, it was found that they would not close under this application alone; but after the cauterising iron had also been applied three times, I had the pleasure to see the fistula heal, and the patient was quite recovered.

PHYSIOLOGICAL AND CHEMICAL RESEARCHES ON THE BLOOD OF THE VENA PORTÆ.

The first number of the forty-fourth volume of *Rust's Magazin* contains an account of some highly interesting researches by Professor Schultz, respecting the chemical and physiological differences between the blood of the vena portæ, and that of the arteries and other veins.

1st. The blood of the vena portæ is in general blacker than other venous blood, although this difference is not always manifest to the sight; it is not reddened by the neutral salts, or exposure to the atmosphere, or by the action of oxygen.

2d. The blood of the vena portæ does not generally coagulate, but when it does, the coagula are less firm than those of the other arteries. In those cases in which it

has coagulated, it liquifies entirely or partly at the end of from twelve to twenty-four hours, and produces, as well as that which does not coagulate, a black sediment, upon which is formed clear serum.

3d. The blood of the vena portæ contains on an average, when fresh, 5·23 per cent., and when dry, 0·74 per cent. less fibrine than the blood of the arteries and the other veins.

4th. The liquid blood of the vena portæ contains generally a little less solid matter (0·18 to 0·3 per cent) than the arterial blood and the other venous blood.

5th. Its serum contains generally 58·1 less solid matter than the arterial serum, and 0·80 less than that of other venous blood. In the dry state, the first is of an ash-grey, the second yellow, the third greenish-yellow.

6th. The blood of the vena portæ contains proportionably more cruor and less albumen; the contrary is the case in the arterial blood. The dry cruor of the vena portæ is brownish-grey, that of the other veins deep red, that of the arteries bright red.

7th. The blood of the vena portæ contains, in its solid parts, almost twice as much fat as that of the arteries and the other veins. The proportion is as follows:—

Blood of the vena portæ ..	1·66	per cent.
Arterial blood	0·92	"
Venous blood of the other veins	0·83	"

8th. The dry serum of the vena portæ contains but 0·27 per cent. more fat than the dry serum of the arteries and the other veins.

9th. The albuminous cruor of the vena portæ contains 1·11 per cent. more fat than that of the arterial blood, and 1·21 per cent. more than that of the blood of the other veins.

10th. It is in the fibrine that this difference is the greatest. The dry fibrine of the vena portæ contains 10·70 per cent. of fat; that of the arteries 2·34 per cent.; so that the difference is 8·36 per cent.

11th. The fat of the blood of the vena portæ is blackish-brown and unctuous; that of arterial blood and other venous blood white, or yellowish-white, and crystalline; that of the white chyle to two-thirds liquid and one-third crystalline.—*American Journal of the Medical Sciences*, Feb. 1836.

Grief is good for none but such as are very fat.—*Ambrose Paré.*

RESPONSIBILITY OF SURGEONS.

The following case will probably be interesting to many readers. It will serve to show what risk is sometimes incurred, even when a professional man, on being called in to a critical case, exercises his best judgment and discretion.

Monmouth, March 29, 1836.—Plaintiff (Walker), an attorney, brought an action against defendant (Jones), a surgeon, to recover damages for unskilful treatment.

On the 2d of June last, plaintiff was attacked with paralysis,—it was a slight attack, merely affecting one of his legs and the corner of his mouth. Mr. Jones attended, prescribed, and sent him medicine. In the middle of the night plaintiff had a fit. Defendant was sent for, and bled the patient copiously. Dr. Morris, of Chepstow, was then called in, who directed leeches to be applied. Plaintiff remained under Mr. Jones's care for two days longer, and took some doses of calomel. On the fourth day, becoming impatient, the plaintiff went to Chepstow, when he put himself wholly under Dr. Morris's care. He remained severely ill, and subjected to very violent remedies, until the end of August, when he recovered.

It was imputed to the defendant, that he ought to have bled the plaintiff in the first instance; the premonitory symptoms being such as clearly indicated the impending attack, which might have been prevented by the timely use of the lancet.

Dr. Morris, however, who was examined for the plaintiff, on cross-examination, admitted that some surgeons do not consider it advisable to bleed in all cases of impending paralysis, and that he could not say that the defendant's conduct, in the present instance, had been unskilful or negligent. — Thereupon the plaintiff submitted to a nonsuit.

NITRO-MURIATIC ACID BATH.

To the Editor of the Medical Gazette.

Sir,

Dr. Sutherland, in your number for the 9th of this month, very laudably vindicated for our countryman, the late Dr. Scot, the credit of having been the first to recommend the use of a nitro-muriatic acid bath in affections of the liver, in opposition to some recent pretensions of a M. Schlesinger, in *Hufeland's Journal*.

My object in troubling you with this note is to correct a slight error into which

Dr. Sutherland has fallen, in supposing that Dr. Scot never published anything on the subject, with the exception of the printed document which he (Dr. Sutherland) forwarded to you. In the eighth volume of the Medico-Chirurgical Transactions, at page 171, he will find a paper by Dr. Scot, "On the Internal and External Use of the Nitro-muriatic Acid, in the Cure of Diseases." It was read to the Society on March 4, 1817, and is dated June 3, of that year—dates sufficiently ancient, I opine, to put out of court any modern German who may claim, at this time of day, the bath as his discovery.

But is the said bath of any use? I once tried it, but it did not seem to effect any change whatever upon the system.

I am, sir,
Your obedient servant,
WM. MACLURE.

MEDICO-CHIRURGICAL TRANSACTIONS.

GENERAL INDEX.

WE have received a copy of the newly-published Index to the first eighteen volumes of the Transactions of the Royal Medico-Chirurgical Society. Every medical man, who is at all conversant with the literature of the profession, must appreciate the advantages of having such a guide, in exploring the excellent things contained in this valuable collection. To Mr. J. F. South, we are indebted, it appears, for the present boon; and that gentleman, for his zeal and diligence, is certainly entitled, not only to the compliment paid him by his fellow members, but to the general thanks of the profession.

ROYAL COLLEGE OF SURGEONS.

JACKSONIAN PRIZE.

THE Jacksonian Prize for the year 1835 has been adjudged to Mr. Frederick Ryland, of Paradise-Street, Birmingham, for a dissertation on "Injuries and Diseases of the Larynx; also of the Trachea; and Treatment."

NOTICES.

"D. R. M." We doubt whether we should have room for the proffered letters of our correspondent: perhaps it were as well not to send them just at present.

Communications from Worcester and Warwick, relative to the meetings of the profession in those towns, have been received: they shall be duly attended to.

Several valuable papers, from various quarters, have been unavoidably postponed, for want of space; but they shall have an early insertion.

LECTURES

ON

MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

BY JON. PEREIRA, ESQ., F.L.S.

LECTURE XXXI.

I PROCEED, in this lecture, to notice the second class of metals; namely, the *electro-negatives*, or those which, when combined with oxygen, form by preference acids. One of the most important of these is

ARSENICUM,

the only pharmacological compound of which is

Arsenious Acid.

History and synonymes.—Arsenious acid, commonly termed *white arsenic*, or the *oxide of arsenic*, is first distinctly mentioned by Geber, who gives more than one process for obtaining it by sublimation. Theophrastus, indeed, speaks of ἀρρενικον, and Dioscorides of ἀρσενικον; but these terms refer to a sulphuret of arsenic.

Native state.—Arsenious acid is found native and uncombined at Andreasburg, in the Harz, and at other places, but is not a common mineral. It never occurs in the organized kingdom.

Preparation.—A few years since nearly all the arsenious acid employed in this country was imported from Germany, whereas now, I am informed, it is principally obtained from Cornwall. Mr. Peters, one of my pupils, and a resident in the neighbourhood of the Cornish arsenic works, tells me there are but two of these works in the county—namely, one at Perran, near the Devran stream-works, and one on the Carnon stream-works,—both near Truro.

The processs for procuring the acid may be divided into two parts: the first consists in roasting the ore; the second in refining it.

(*a.*) The *roasting* is performed in Cornwall in a reverberatory furnace,—in Silesia, in a kind of mufiling furnace. The ore employed varies at different places. At Altenburgh, in Silesia, it is *arsenical pyrites*, or *mispickel* (a compound of 1 atom arseniet of iron, and 1 atom sulpho-arsenite of iron), whereas at Reichenstein, in the same country, it is *sesquiarseniet of iron*. In Saxony it is obtained as a secondary product in the roasting of cobalt ores; and in Cornwall, Mr. Peters tells me, the ores of copper are employed. By this process the metallic arsenicum is oxidized, and converted into arsenious acid, which is volatilized, and afterwards condensed in a pulverulent form in chambers attached to the furnaces.

(*b.*) The *refining* is effected in cast iron pots, to which cylindrical iron heads are attached, which at the tops are contracted into cones, each terminating in a pipe made of sheet-iron. Heat is then applied for twelve hours, by which the arsenious acid is sublimed and condensed on the sides of the iron head.

Properties.—When recently prepared, arsenious acid is in the form of large, glassy, transparent cakes, sometimes colourless, at others having a yellowish tinge. Frequently the cakes consist of concentric laminæ, formed by the successive sublimations. Most curiously, these masses soon become opaque and white externally, like enamel, the opacity gradually extending towards the centre; and in some cases the acid becomes friable and pulverulent. Now what can be the cause of this change? I do not believe that the masses gain any increase in weight, and, therefore, they cannot become hydrated, as Krüger fan-

cies. Professor Guibourt suspects that the acid absorbs ammonia from the air, though he was unable to prove it. He also states that the specific gravity, the solubility, and the acid properties, of the opaque and transparent varieties, are different.

Transparent Arsenious Acid.

Sp. gr. 3·7385 (or 3·7391.)
Soluble in 103 parts of water at 59°.
Soluble in 9·33 parts of water at 212°.
Its solution feebly reddens litmus.

Opaque variety.

Sp. gr. 3·695.
Soluble in 80 parts of water at 59°.
Soluble in 7·72 parts of water at 212°.
Its solution restores reddened litmus.

But I find that both kinds redden litmus, and Dr. Christison has observed the same. I think, therefore, that as we have no ground for asserting their composition to be different, we ought to regard them as isomeric compounds. Arsenious acid has little or no taste, as Plenck, Addington, and Christison, have remarked; and neither in the solid nor vaporous form has it odour. We may readily obtain the acid in a crystalline condition by sublimation or solution: the crystals are usually regular octahedrons. It is of importance to know that the presence of organic matters very much impairs the solvent power of water for this acid; a circumstance which readily explains why no arsenious acid has, in some cases, been found in the liquid contents of the stomachs of persons poisoned by it.

Composition.—This acid is composed of—

	Thomson.		*Berzelius.*	
Arsenicum	1 atom	= 38	2 atoms	= 75·33
Oxygen	$1\frac{1}{2}$ atoms	= 12	3 atoms	= 24·03
		50		99·66

Characteristic tests.—This part of our subject will be most conveniently examined under three heads: first, the tests for a clear solution of arsenious acid; secondly, the tests for solid arsenious acid in its pure unmixed form; and thirdly, the tests for arsenious acid when mixed with organic substances, such as the contents of the stomach.

1. *Tests for a clear Solution of Arsenious Acid.*

A considerable number of tests have been proposed, but only four deserve much notice; namely, *ammoniacal nitrate of silver*, *ammoniacal sulphate of copper*, *sulphuretted hydrogen*, the *reduction process*, and the formation of *arsenietted hydrogen*.

(*a.*) *Ammoniacal nitrate of silver.*—We are indebted to Mr. Hume (late of Long Acre) for this test, and hence it is frequently termed *Hume's test.* The mode of preparing it is this: add a few drops of *liquor ammoniæ* to a solution of nitrate of silver, so that the oxide of silver which the alkali at first throws down may be nearly but not entirely redissolved. Great care is requisite to add neither too much nor too little; for if too much be employed, the solution will not occasion any precipitate with arsenious acid; and if too little, it will produce a precipitate with phosphate of soda similar in colour to that produced with arsenious acid. The only certain way of knowing when the proper quantity has been employed, is to test it: arsenious acid, but not phosphate of soda, ought to occasion a precipitate with it. When a solution of arsenious acid, and of ammoniacal nitrate of silver, are mixed, two new compounds are formed,—nitrate of ammonia in solution, and the yellow arsenite of silver, which precipitates. The substance most easily confounded with arsenite of silver is the yellow phosphate of silver; but if the test have been properly prepared, the nitrate of ammonia will keep the phosphate in solution. If the suspected liquid contain a free acid (as nitric, acetic, citric, or tartaric), the arsenite will not precipitate until the acid be saturated, when it readily separates.

There are two objections to this test, which very much diminish its value: if any chlorides be present (common salt, for example), we get a white precipitate of chloride of silver, even though the suspected liquid contains a considerable quantity of arsenious acid. To obviate this difficulty, you must proceed thus: before applying the test add a few drops of nitric acid, and then an excess of a solution of nitrate of silver. By this means the chloride salt will be got rid of, while the arsenious acid is left in solution. The liquid is then to be filtered, to remove the precipitated chloride of silver, and the test applied to the clear liquor. It is necessary I should caution you against an optical fallacy: I have here a yellow liquid, to which I shall add a little common salt, but no arsenious acid. If now ammoniacal nitrate of silver be applied, a white precipitate is produced, which, seen through a yellow medium, has been mistaken for a yellow precipitate. The second objection to this test is, that the presence of much organic matter will impede its proper action.

(*b.*) *Ammoniacal sulphate of copper.*—This test is prepared by cautiously adding *liquor ammoniæ* to a solution of sulphate of

copper, so as to redissolve the oxide of copper which it at first throws down. Care must be taken not to add more alkali than is necessary, otherwise the liquor will not precipitate arsenious acid; and to use dilute liquids, for a concentrated solution of the ammoniacal sulphate, will not produce the desired effect. When we mix, properly prepared, ammoniacal sulphate with arsenious acid, a green precipitate of the arsenite of copper falls down, while sulphate of ammonia remains in solution. The objections to this test are, that astringents prevent its action; and thus, if the poison were taken in tea, this test would not detect it. Secondly, yellow coloured and other fluids of an organic nature, give a greenish tinge and slight precipitate, even though no arsenious acid be present.

(c.) *Sulphuretted hydrogen.* — If this gas (now usually termed hydrosulphuric acid) be passed through a solution of arsenious acid, a yellow precipitate of sesquisulphuret of arsenicum (orpiment) is produced, while the oxygen of the arsenious acid and the hydrogen of the sulphuretted hydrogen unite to form water. In order, however, for this effect to be produced, it is necessary that the liquid be slightly acidified by acetic acid. If the liquid be already acid, we must neutralize it by cautiously adding an alkali, and then acidify by acetic acid.

In performing the above operation, applying this test we may place the suspected liquid in a test-tube, or conical wine-glass; the gas being developed in a common Florence flask (or two-necked bottle, as recommended by Dr. Christison:) the mouth of the flask is closed by a cork, perforated by a tube curved twice at right angles. The ingredients for developing the gas are a metallic sulphuret (as of iron or of antimony), and sulphuric or hydrochloric acid. I prefer the sulphuret of iron and sulphuric acid diluted with about an equal volume of water. These are to be introduced into the flask previous to the adaptation of the cork. After the gas has passed through the arsenical liquid for a few minutes, portions of the sesquisulphuret of arsenicum begin to fall down, and the separation of the precipitate is promoted by acetic acid, by exposure to the air, and by ebullition.

Sulphuretted hydrogen produces a somewhat similar yellow-coloured precipitate with *solutions of cadmium*, *of the persalts of tin*, *of selenic acid*, and with the *antimonial compounds*; for example, with *tartar emetic*. As *cadmium* has sometimes been found in the preparations of zinc, you ought to be aware of the possible fallacy of sulphuretted hydrogen as a test for arsenious acid. I have never met with any of the pharmaceutical preparations of zinc contaminated with cadmium; but "during the apothecaries' visitation in the state of Magdeburgh, there was found, in the possession of several apothecaries, a preparation of zinc from Silesia, made in Hermann's laboratory, at Schönebeck, which was confiscated, on the supposition that it contained arsenic, because its solution gave a yellow precipitate with sulphuretted hydrogen, which was considered as orpiment. This statement could not be indifferent to M. Hermann, as it affected the credit of his manufactory; especially as the medical counsellor, Roloff, who had assisted at the visitation, had drawn up a statement of the circumstances which occasioned the confiscation, and caused it to be published in Hufeland's Medical Journal. He subjected the suspected oxide to a careful examination, but he could not succeed in detecting any arsenic in it. He then requested Roloff to repeat his experiments. This he did; and now perceived that the precipitate which he had taken for orpiment, was not so in reality, but owed its existence to the presence of another metallic oxide, different from arsenic, and probably new. Specimens of this oxide of zinc and of the yellow precipitate were sent to Stromeyer for examination, who readily recognized the presence of cadmium, and was able to extract from it a considerable quantity of that metal."

In regard to the *persalts of tin*, you should be aware that the perchloride which is sold for the use of dyers, under the name of the *permuriate* or *spirit of tin*, occasions a yellowish precipitate of the bisulphuret of tin, somewhat resembling sulphuret of arsenicum.

If sulphuretted hydrogen be passed through a weak solution of *tartar emetic*, we obtain a precipitate usually reddish, but sometimes a yellowish liquid is formed, not distinguishable by its colour from that produced with arsenious acid. I am aware that my friend, Dr. Christison, says that both he and Dr. Turner never saw the antimonial precipitate assume the yellow colour of sesqui-sulphuret of arsenic. But I have been accustomed, for years, to show in lecture the similarity of the two precipitates. [The experiment was here shown.] You observe that to produce this effect I have employed a very dilute solution of tartar emetic, and have passed sulphuretted hydrogen through it for a few seconds only. If I now pass more gas through it, the colour of the liquid becomes redder. Antimonial preparations containing the peroxide of this metal, occasion paler-coloured precipitates with sulphuretted hydrogen than tartar emetic does.

Hydrosulphuret of ammonia. — Sometimes the hydrosulphuret of ammonia is em-

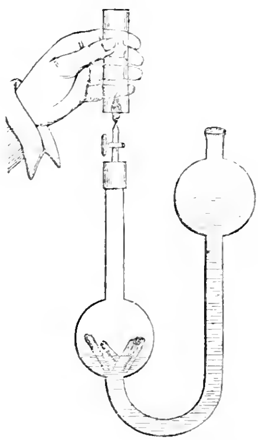
ployed instead of sulphuretted hydrogen gas. In that case, an acid should be added at the time of employing it, to neutralize the ammonia. In the hands of an experienced experimenter, it is sometimes a good test; but it is liable to some fallacies which might deceive persons unaccustomed to chemical manipulation. One most important objection to it, is, that if kept in a bottle only partially filled, it undergoes some chemical changes; in consequence of which its reaction on the metals is modified. I accidentally discovered this: I find that if two or three drachms of the hydrosulphuret be exposed to the air for a day or two in a wine-glass, it becomes covered with a thin film of sulphur, and acquires the power of precipitating a solution of the acetate of lead *red*, and of tartar emetic *yellow*.

(*d.*) *Reduction process.*—This is by far the best and most certain means of recognizing arsenious acid. To perform this process, sulphuretted hydrogen is to be passed through the suspected solution, (as described when noticing the last test) and the yellow sesquisulphuret of arsenic which precipitates, to be carefully collected, dried, mixed with a little charcoal and carbonate of potash, or of soda, and introduced into a test-tube, the best form for which is one having a narrow neck, with a small bulb at the end. An intimate mixture of charcoal and carbonate of potash is readily procured by heating the bi-tartrate of potash in a crucible, until no more volatile matter is evolved: the residue is termed *black flux*. Instead of this, a mixture of two parts ignited carbonate of soda, and one of charcoal, may be employed. The mixture of arsenious acid, alkaline carbonate, and charcoal, is then to be heated by a spirit-lamp: the sulphur of the arsenical sulphuret uniting with the metallic base (sodium, or potassium) of the alkali, forms a sulphuret, and the metallic arsenicum is volatilized and condensed, forming a brilliant crust on the side of the tube. The characters of the arsenical crust are, the brilliancy of the outer surface, which is frequently equal to polished steel, or looking-glass; the crystalline appearance, and greyish-white colour, of the inner surface of the crust; its volatility; and its conversion into octahedral crystals, (arsenious acid) when sublimed up and down the tube.

If the metallic crust be well formed, the characters just mentioned are sufficient to recognize it: but on some occasions these appearances are only imperfectly presented. Thus when the arsenical sulphuret has been mixed with a little animal matter, the metallic character of the sublimed arsenic may be completely masked; and it may be impossible to decide merely by physical examination, whether the black crust be metallic arsenic, or a carbonaceous substance. Whenever, therefore, the least doubt is entertained, you must seek for further evidence of the existence of the metal. For this purpose, let the narrow portion of the tube which contains the crust, be cut off by a file, and having roughly powdered it, introduce into another tube, and apply heat. Or we may dissolve the suspected crust in nitric acid, and evaporate to dryness, by which we obtain arsenic acid: this is easily recognized by adding a solution of nitrate of silver, by which a brick-red precipitate of arseniate of silver is produced. This arseniate may be reduced, if necessary, by mixing it with charcoal and boracic acid, and heating in a glass tube.

(*e.*) *Formation of arseniuretted hydrogen**.—If a liquid containing a small portion of arsenious acid, or arsenite of potash (Fowler's solution answers very well), be added to the ingredients for generating hydrogen gas (namely, water, zinc, and sulphuric acid), we obtain hydrogen and arseniuretted hydrogen gases. The latter may be recognized by the following characters: the colour of the flame, which is bluish white; by burning it from a small jet pipe, within a narrow glass tube, a deposit of white arsenious acid, and of the brown hydruret of arsenicum, is formed on the side of the tube, while an alliaceous odour is very evident. Here is a drawing of the apparatus which I have employed for this experiment, but I think it is susceptible of improvement.

FIG. 97.



* This test I have only lately become acquainted with. Mr. Button, of the firm of Dymond and Co. Chemists, Holborn, tells me it was discovered by

I have not added less than $\frac{1}{20}$ of a grain of arsenious acid, but I am told $\frac{1}{150}$ of a grain will suffice; and I do not doubt the correctness of the information, seeing, that with $\frac{1}{20}$ of a grain I could make at least twenty experiments, and each time detect the arsenic, so that the quantity consumed in each experiment could not be more than $\frac{1}{400}$ of a grain.

Having some liquid in my possession, which had been removed from the stomach of a man poisoned by arsenious acid, and which, of course, contained animal matter, I introduced a portion of it into the apparatus, and readily detected the arsenic, by the means first mentioned, so that the presence of organic substances did not impede the action of the test. And I ought to remark, that this liquid gave no indication of arsenious acid with the ammoniacal sulphate of copper, nor with ammoniacal nitrate of silver, though sulphuretted hydrogen produced a yellow precipitate with it.

An objection to the test is, that with organic matters the liquid is apt to froth a great deal, by which it is difficult to obtain a good jet of gas; however, I, in part, obviated this, by adding a little alcohol, and evolving the gas very slowly. I have no doubt that an alteration in the form of the apparatus would partly counteract this.

2. *Tests for Solid Arsenious Acid.*

Solid arsenious acid is easily recognized by the following characteristics:—

(*a.*) *Its volatility.* — If I place on the point of a penknife a small portion of this acid, and introduce it within the flame of a spirit-lamp, you will observe that it is easily volatilized, and produces a white smoke. However, several other substances have a similar property: for example, *sal ammoniac.*

(*b.*) *The garlic odour of the vapour of metallic arsenicum.*—If a red-hot cinder be placed in a saucer, and a small portion of arsenious acid be thrown on it, the carbon of the cinder deoxidizes the acid, and the resulting metallic arsenicum is converted into vapour, which may be recognized by its garlic smell. But the test is not one of much value; for the garlic smell may be masked by the presence of organic matters, as flour, which, in burning, develops a strong odour; and, on the other hand, this smell is not peculiar to arsenious acid, since phosphorus, and some other bodies, give it out when heated. Vauquelin, Barruel, and Orfila, have shewn that a compound of albumen and fat, which evolved this odour when heated, did not contain a particle of arsenious acid. "It is true," say these experimenters, "that arsenicum does evolve a garlic odour when volatilized; but even when this is well characterized, it is insufficient to establish the existence of the oxide of arsenic, since it belongs to some other substances; and it is not impossible that there may be developed in the stomach, during digestion, substances which exhale an analogous odour, when heated."

(*c.*) *The reduction process.* — If arsenious acid be mixed with charcoal, or back flux, and heated in a glass tube, a metallic crust of arsenicum will be obtained, possessing the properties already described.

(*d.*) *Formation of Scheele's green.*—If a small portion of arsenious acid be added to a weak solution of the ammoniacal sulphate of copper, a green precipitate of the arsenite of copper (Scheele's green) will be gradually formed.

(*e.*) *Liquid tests.*—Dissolve the acid in water; apply the liquid tests already described. The ammoniacal nitrate of silver will readily distinguish the arsenious from arsenic acid, since it produces a yellow precipitate with the one, and a red precipitate with the other.

3. *Tests for Arsenious Acid mixed with Organic Substances.*

The most important and difficult part of our subject remains yet to be examined; I mean the recognition of arsenious acid when mixed with organic substances, such as the contents of the stomach.

Sometimes you may observe in the stomach a white powder, or white particles: these are, of course, to be carefully removed; and if they are arsenious acid, no difficulty will be experienced in recognizing them by the tests already mentioned.

If no solid arsenious acid be recognized, we must cut the stomach into small pieces, and boil along with the contents of this viscus for half an hour, in distilled water, to which a little liquor potassæ has been added: then filter, first through muslin, then through paper. Fibrine is insoluble in water, and by boiling albumen is coagulated, so that (with the exception of small portions of these principles held in solution by the alkali) the filtered liquor is free from both fibrine and albumen. A little acetic acid is now to be added, and the liquid boiled, by which any caseum present will be coagulated, and got rid of by filtering a second time. Sometimes the liquor is now found sufficiently free from organic matters to enable us to detect the arsenious acid very

Mr. Marsh, of Woolwich, who is already known to the public, as having made some improvements in electro-magnetic apparatus.

readily. Dr. Christison says, that if the ammoniacal-nitrate of silver acts characteristically, (that is, gives a copious yellow precipitate) the liquid is sufficiently free from foreign matter. If it does not, evaporate to dryness by a gentle heat, and boil the residue in repeated portions of distilled water. We shall thus obtain an arsenical solution, which is to be decomposed by passing sulphuretted hydrogen gas through it, and the resulting sesquisulphuret reduced, as already described.

Another means of recognizing arsenious acid, when mixed with organic matters, is the formation of arseniétted hydrogen, already noticed.

Physiological effects.—I propose to take a general review of the operation of arsenious acid on the organized kingdom, under three heads—first, its effects on vegetables; secondly, its effects on animals generally; and, thirdly, its effects on man.

1. The *effects of arsenious acid on vegetables* have been studied by Jäger, Seguin, Marcet, Macaire, and others; and from their observations we learn that it is poisonous to all families of plants. It appears that seeds which have been immersed in a solution of it are incapable of germinating, and that buds which have been plunged in it are no longer capable of developing. When roots or stems are immersed, the death of the plant occurs, preceded by drooping and alteration of the colour of the leaves, as well as of the petals. If the stem of the common barberry (*berberis vulgaris*) be placed in dilute hydrocyanic acid, or in an aqueous solution of opium, the stamens lose their remarkable contractile power, but remain flexible. If, however, we employ a solution of arsenious acid, the plant equally dies, but the stamens become stiff, hard, and retracted, and on any attempts being made to alter their position, they readily break. These curious facts seem to prove that the effects produced by this acid on vegetables are very different from those caused by hydrocyanic acid and opium; for the latter seem to exhaust the irritability, while the former seem to give rise to a condition very analogous to the spasm of animals.

2. The *effects of arsenious acid on animals generally* are interesting, and have been the subject of numerous experiments, some of which are recorded in Wibmer's work "*Die Wirkung der Arzneimittel und Gifte.*" On every animal on which the operation of this acid has been tried, the effects have been poisonous. Jäger has published an elaborate account of the toxicological effects of this substance on the different classes of animals; and from his experiments we learn that death is always preceded by inordinate actions and increased evacuations, especially from the mucous membranes. In most animals the stools were frequent and fluid; and in those in which mucus is secreted on the surface, it was remarkably increased. The power of voluntary motion and susceptibility of external stimuli were decreased; and after death the muscles soon ceased to be influenced by the galvanic agency. In animals that breathe by lungs, respiration became difficult and laborious; and in warm-blooded animals great thirst was experienced. In birds and mammals convulsions came on, preceded by vomiting, except in those animals (as the rabbit) which cannot vomit.

3. The *effects of arsenious acid on man* now require our attention; and I propose to examine this part of our subject under three heads.

(*a.*) *In very small* or *therapeutical doses* (as the 16th or 12th of a grain), no injurious effects are usually observed, unless the acid be taken for a long period; indeed, some writers go so far as to assert that in this dose arsenious acid is a strengthening remedy, that it improves the appetite, invigorates digestion, promotes assimilation and secretion, excites the muscular and nervous functions,—in a word, acts as a *tonic.* I cannot, however, subscribe to this doctrine, because I have never been able to see the effects here asserted. It is, indeed, true that patients sometimes experience a temporary increase of appetite from the use of small doses of arsenic; and it is also certain that this remedy is frequently beneficial in agues, and other diseases in which tonics have been found efficacious. But the analogy between the action of arsenious acid and that of the vegetable tonics (as cinchona, to which Vogt compares it) stops here. I have sought in vain for other evidences of a tonic operation. I have seen very minute doses of arsenic given to patients affected with lepra, and continued for many days, without being able to detect the least indication of its action on the system, except the amelioration of the disease. When the dose was slightly increased, the appetite in some cases appeared to increase; but this effect was neither universal nor continued. Very shortly afterwards nausea, or even vomiting, came on; a febrile condition of the body was set up; the patients usually complained of great languor and inaptitude for employment; and sometimes these symptoms were accompanied or followed by redness of the eyes and swelling of the face: effects which are so different from those produced by the remedies called strengthening, that I cannot regard arsenic as a tonic. In proof of the beneficial effects of this substance, we are gravely told that the country people of upper Styria, in Austria, use arsenic as a

stomachic, and as a condiment for many kinds of food,—for example, cheese; and a healthy peasant himself tells us that he was accustomed to take two grains of arsenic daily, without which, he assures us, he could not live! In further proof of this strengthening action of arsenic, Vogt says that it promotes the appetite, the activity, and the power of old enfeebled horses, and mentions that Jäger noticed the same effects on a pigeon. To the first of these statements, namely, the beneficial effects from the use of arsenic as a condiment, I must confess I cannot give credence; and, with respect to its action on horses, it is, I believe, well established that it acts as a virulent poison on these animals. On this point, however, I have already offered a few remarks in a former part of the course*.

(*b.*) *Slow*, or *chronic poisoning*, by arsenious acid next deserves our notice. The long-continued use even of the already noticed small or therapeutical doses will ultimately produce disease, and even death. Sometimes the digestive apparatus, at other times the nervous system, first shews symptoms of the poisonous operation. But let me offer a case by way of illustration.

A gentleman affected with lepra, for whom I had prescribed a few drops of the liquor arsenicalis, to be taken twice daily, not observing any effect, thought proper to increase the dose without consulting me. In a few days he became very unwell, though he did not suspect the cause, and without being able to tell precisely what was the matter with him. I found him listless and dull, indisposed for business, and with great depression of his muscular power: he complained of loss of appetite, thirst, and want of sleep; his limbs trembled, his skin was hot, and his pulse quick; occasionally he experienced cramps in his legs. I had no doubt these symptoms were brought on by the use of the arsenic, and therefore, of course, ordered him immediately to suspend its use, which he did, and in a few days he was quite restored.

Now, this case is an apt illustration of the gradual progress made by this poison in destroying health, and, if persevered in, of causing death. You will not, therefore, be surprised, to find that it has been employed to produce slow poisoning; and its effects have been very concisely, though graphically, described by Hahneman, (and which I quote from Dr. Christison's work) as follows:—"There are," says he, "a gradual sinking of the powers of life, without any violent symptom; a nameless feeling of illness, failure of the strength, an aversion to food and drink, and all the other enjoyments of life. Dropsy closes the scene, along with black miliary eruptions and convulsions, or colliquative perspiration and purging."

On some occasions, the first symptoms which I have observed of its poisonous operation, have been thirst, redness of the conjunctiva and eyelids, followed by an eruption. At other times, irritation of stomach is the leading symptom. In some cases ptyalism is brought on. Marcus, in the Ephemerides for 1809, has noticed this effect: and in the 16th volume of the MEDICAL GAZETTE, you will find five cases reported by Mr. Furley, in which salivation was observed.

The following is an abstract of the morbid symptoms produced by the continued employment of small doses of arsenious acid, but which are more or less modified in different cases:—Disorder of the digestive functions, characterized by flatulence, sensation of warmth, or actual pain, in the stomach and bowels; loss of appetite; thirst, nausea, and vomiting; purging, or at least a relaxed condition of the bowels; furred tongue, with dryness and tightness of the mouth and throat, or with salivation. The pulse is quick, small, and sometimes irregular; the respiration oppressed, and accompanied with a dry cough. The body wastes; the stomach being frequently so irritable that no food can be retained in it. Headache, giddiness, and want of sleep, are sometimes observed. The limbs become painful, feeble, trembling, subject to convulsions; occasionally benumbed, and ultimately becoming paralyzed. The cutaneous system, in some cases, becomes affected, an eruption makes its appearance, and now and then the hair and nails fall off. Swelling of the feet and of the face is not unfrequently observed; and under these symptoms the patient gradually sinks, in some cases retaining his consciousness to the last, but at other times delirium or stupor being present.

(*c.*) *Acute poisoning by arsenious acid* does not always present the same phenomena. In some cases, the principal or leading symptoms are those indicating gastro-enteritis; the nervous system being not obviously affected, or at least only slightly. In other cases, the gastro-enteritic symptoms are absent, and the principal operation of the poison is on the vascular and nervous systems. Lastly, there are other cases in which we observe both gastro-enteritic disorder with the affection of the nervous and vascular systems.

1. *Acute poisoning, with symptoms of gastro-enteritis.*—Some time after swallowing arsenious acid, nausea and vomiting come on, attended with burning pain in the

* MEDICAL GAZETTE, vol. xvii. pp. 6 and 7.

throat and stomach, and which soon extends over the whole abdomen. Pain and vomiting, however, are not invariably present. The matters vomited vary in their nature and appearance; sometimes being bilious, at other times tinged with blood. Frequently there is a sense of heat, dryness, tightness, and constriction of the throat; accompanied with incessant thirst, and occasionally with an almost hydrophobic difficulty of swallowing. The lower part of the alimentary canal soon becomes affected, indicated by the burning pain, which is increased on pressure—by the hard and tense condition of the abdomen—by the diarrhœa (the stools sometimes being bloody)—by the tenesmus, and by the occasional heat and excoriation of the anus. When the lower part of the alimentary canal is powerfully irritated, the urino-genital apparatus becomes affected; and thus we sometimes find difficulty in passing the water, with burning pain in the genital organs. The constitutional symptoms are, in part, such as you might expect from this violent local disorder: thus the pulse is quick, but at the same time small, feeble, and irregular; cold clammy sweats; the action of the heart is irregular, giving rise to palpitation; the breathing is short, laborious, and often painful; the tongue is dry and furred; and the membrane lining the air-passages feels hot, and oftentimes painful.

Although, in this form of acute arsenical poisoning, the gastro-enteritis is the principal, and in some cases almost the only affection, yet there is generally observed some symptoms indicative of disorder of the cerebro-spinal system: sometimes in the form of tremblings or cramps of the limbs, or delirium, and even, in the last stage, insensibility. Occasionally, also, eruptions take place.

In this form of poisoning, death usually occurs in from twenty-four hours to three days after the administration of arsenic; but Dr. Christison says that Pyl has recorded a case where death occurred in three hours after swallowing the poison.

2. *Acute poisoning, with disorder of the cerebro-spinal and vascular systems, without any remarkable symptoms of gastro-enteritis.*—In both man and other animals arsenious acid occasionally acts as a narcotic poison, there being little (or even no) pain, vomiting, or purging. The symptoms in these cases are usually faintness, or perhaps actual syncope, convulsions, or paralysis; and sometimes insensibility, at other times delirium. When these symptoms occur, they constitute the state called *narcotism*. Of this form of arsenical poisoning (which is somewhat rare), Dr. Christison has given an abstract of twelve recorded cases. In most of them the quantity of arsenious acid taken was large,—as half an ounce, or even an ounce.

3. *Acute poisoning, with symptoms of gastro-enteritis, followed by an affection of the cerebro-spinal system.*—The gastro-enteritic symptoms are such as I have already noticed in speaking of the first kind of acute arsenical poisoning, and, therefore, need not be again described. When, from the smallness of the quantity of the poison swallowed, or from other circumstances, the patient recovers from the gastro-enteritis, symptoms of cerebro-spinal disorder sometimes make their appearance. The kind of disorder, however, varies considerably in different individuals. "The most formidable," says Dr. Christison, "is coma; the slightest, a peculiar imperfect palsy of the arms or legs, resembling what is occasioned by the poison of lead; and between these extremes have been observed epileptic fits, or tetanus, or an affection resembling hysteria, or madness."

The *morbid appearances* produced by arsenious acid next require to be noticed. When arsenious acid kills by its narcotic operation (constituting the second kind of arsenical poisoning which I have described), no morbid condition is observable after death. In other cases, however, various alterations are observed, which may be most conveniently arranged under the following heads:—

(*a.*) *Morbid appearances of the alimentary canal.*—The alterations observed in the condition of the intestinal canal vary with the quantity of the poison taken, and probably with other circumstances, but they are all indicative of inflammation: thus we have redness as one symptom, sometimes accompanied with extravasations of blood into the tissue of the canal; ulceration is also frequently observed, sometimes softening of the mucous coat, effusion (of lymph or blood), and occasionally even gangrenous spots.

(*b.*) *Morbid appearances of the vascular system.*—The blood is sometimes, though not invariably, fluid after death, and dark coloured. The heart is mostly flabby, and it is asserted that on its inner surface (especially the carneæ columnæ and valves, particularly of the left side), is redness, sometimes diffused, sometimes in the form of spots, and which penetrates a line in depth into the substance of the heart. The pericardium usually contains serum.

(*c.*) *Morbid appearances of the respiratory system.*—These are neither very remarkable nor constant, and principally consist in redness of the pleura, effusion of lymph or serum into the cavity of the pleura, red spots, and occasional congestion of the lungs, and redness of the membrane lining the air tubes.

(*d.*) The *morbid appearances of other parts* deserve little attention. In some cases inflammation, and even gangrene, of the *genital* organs have been observed; the *conjunctiva* is sometimes very vascular; and alterations are occasionally observed in the condition of the skin. Redness, extravasation of blood, and effusion of serum, are said to have been seen in the *brain*.

(*e.*) *Influence of arsenious acid on the putrefactive process.*—This I shall examine in the next lecture.

ON THE

POISONOUS PROPERTIES OF HEMLOCK,

AND ITS ALKALOID CONIA *.

By Robt. Christison, M.D. F.R.S.E.

Professor of Materia Medica in the University of Edinburgh.

[Concluded from p. 128.]

I have in vain attempted to settle the point—whether conia is the true active principle of the plant—by reference to the existing descriptions of the effects of hemlock by toxicological authors. Passing by, for the present, the statements of ancient authors, which will be reverted to afterwards, and proved not to be confidently referrible to the modern hemlock, we come first to the older modern writers, such as Matthioli and Kircher. The former says, a vine-dresser and his wife, who ate hemlock roots for parsnips, became so delirious, that they ran about the house, frantically knocking themselves against every thing in their way; and the latter says, two monks from the same cause became raving mad, plunged into a pond, taking themselves for geese, and suffered long after from incomplete palsy and muscular pain †. It is difficult, certainly, to connect these narratives with the preceding details of the action of conia. As little connexion can be traced with the matter-of-fact narratives of cases in more recent times, which all point at delirium, coma, and convulsions, as the leading symptoms. These cases, however, are limited in number; few are minutely described; several occurred before physicians had learned to discriminate accurately the external characters of the true hemlock, and other poisonous umbelliferous plants resembling it; in scarcely any of them is allusion made to the risk of error from this cause, or any pains taken to establish the identity of the poison; and in some, including one related by myself, which occurred twelve years ago, the symptoms were taken at second hand, the individuals having died before being seen by a competent observer. The resemblance subsisting between hemlock and various umbelliferous plants, such as *Cicuta virosa*, *Æthusa cynapium*, *Œnanthe crocata*, *Chærophyllum temulentum*, is alone sufficient to vitiate most of the modern descriptions of the poisonous effects of the first species. We know that they often have been confounded together; and hence we can have no certainty what the plant was in special cases of poisoning, where the name merely is given, and the narrative does not contain internal evidence of its exact nature. Singular, then, as it may appear, we are very imperfectly acquainted with the real effects of one of our most familiar poisons on the human body.

For the like reasons, our knowledge of the effects of hemlock on the lower animals is far from being precise or positive. The only unequivocal experiments, indeed, are those of Professor Orfila, and a few performed by Professor Schubarth *; and from these we should infer, that, besides possessing irritant properties, hemlock induces giddiness, convulsions, loss of sensibility, palsy, and coma. This account does not agree with the account given above of the action of conia, which does not seem to affect the senses so long as the respiration goes on. But it is possible that the difference is more apparent than real, and that hemlock has been supposed to extinguish sensation, merely because, by inducing general paralysis, it takes away the power of expression. At least, in some experiments I have made, sensation did not appear to be affected; and the whole phenomena were identical with those produced by conia. In these experiments I used very strong extracts prepared by absolute alcohol from the fresh leaves, or the full-grown seeds; and each of them occasioned, in doses of thirty grains or thereabouts, paralysis of the voluntary muscles, with occasional slight convulsions, then paralysis of the respiratory muscles of the chest and abdomen; and, finally, cessation of the action of the diaphragm; sensation appeared to continue so long as it was practicable to make an observation on the subject; and the heart contracted vigorously for a long time after death. From these extracts a very powerful odour of conia was disengaged by caustic potassa.

---

* Transactions of the Royal Society of Edinburgh, vol. xiii. *just published*.

† Wibmer, die Wirkung der Arzneimittel und Gifte, i. 172.

* Horn's Archiv für Medizinische Erfahrung, 1824.

It seems to me clear, therefore, that the action of conia and of hemlock are identical, or nearly so; and that conia is either the active principle of the plant, or contains it in a modified form.

I wish I could have added to these observations on the poisonous effects of conia and hemlock, some account of their physiological properties in small doses. This branch of the inquiry into their action I have not yet been able to investigate. It cannot be pursued with any accuracy by experiments on the lower animals. The phenomena must be ascertained in the human subject chiefly, which I have not hitherto been able to accomplish. On this head it may merely be observed, that, if physicians or physiologists would acquire definite information as to the physiological effects of hemlock in small or medicinal doses, they must begin the inquiry anew. Little importance can be attached to any thing already done in this field, as I have no doubt whatever, that by far the greater proportion of the preparations of hemlock hitherto employed have been of very little energy, and in the doses commonly used are absolutely inert.

Having now accomplished the chief object of this paper, I ought, perhaps, to conclude; but there is a topic remotely connected with it, to which I may be allowed briefly to advert.

I have several times been asked by my literary friends what the poison could have been which was used by the ancient Greeks, and particularly the Athenians, for putting state-criminals to death. This question has engaged the attention of many commentators, and of some modern physiologists attached to the literature and medicine of the classic ages; and the general result has been a belief that our hemlock, the *Conium maculatum* of botanists, is the *Cicuta* of the Romans, the Κωνειον of the Greeks, and the Athenian state-poison. Others, however, have doubted the correspondence here supposed. And, although the adoption by modern botanists of the term *Conium*, for designating the genus to which our spotted hemlock belongs, may seem to set the matter at rest, the question is really far from settled; and the proofs given above of the erroneous or imperfect ideas entertained, even in the present day, of the effects of hemlock, would reopen it even if it had been closed.

This inquiry is obviously one of much interest to every scholar and physician; for, on the one hand, it involves the identification of an ancient medicine of no mean repute; and, on the other, it tends to enliven our conceptions of one of the most interesting periods of classic history, by enabling us to point to a known substance as the poison by which Socrates and Phocion died.

In considering the subject, it is right to inquire, in the first place, whether our knowledge of the botanical and poisonous properties of hemlock corresponds with what ancient medical authors have said of the plant Κωνειον. Here we ought to be at no loss, for both Pliny and Dioscorides have left tolerably minute descriptions of the plant; and Nicander, in his poetical treatise on poisons, has described its effects on the body, and been followed in his description by succeeding writers. Dioscorides, in his fourth book, thus lays down its botanical characters:—"The plant Κωνειον produces a tall stem, jointed like that of fennel (*Anethum fœniculum*); leaves like the ferula (*Ferula communis*), but narrower, and of a heavy smell; branch shoots and umbels at the summit; a whitish flower; a seed like that of anise, but whiter; a hollow root, not deep." The description given by Pliny of the cicuta, which is well made out to have been the Greek Κωνειον, follows closely that of Dioscorides. "The stem . . . . is smooth, jointed like a reed, blackish, taller frequently than two cubits, very branchy at top. The leaves are more tender than those of coriander, of a heavy odour; the seed thicker than anise; the root hollow."

Now it appears to me impossible to refer the plant by these descriptions to the modern *Conium maculatum*. The description of the stem, leaves, summit, flower, and seed, is so vague, that it will apply to twenty umbelliferous species as well as to our hemlock. Pliny's term *nigricans*, applied to the stem, is but a feeble approach to the very remarkable character of the modern plant, the purple-spotted stem,—a character so obvious, that one can scarcely imagine an ancient herbalist omitting it in taking a description from an actual specimen. Leaves narrower than those of ferula, more tender than those of coriander, if modern scholars and physicians are right in so translating the Greek ναρθηξ, and the Latin *coriandrum*, cannot be held to designate with any accuracy the leaves of our conium; and still less will the *radix concava* of Pliny, the ριζα κοιλη και οὐ βαθεια of Dioscorides, designate its root, which is perfectly solid, and even at the present season (December), when the plant is young, very commonly penetrates twelve or fifteen inches into the soil. Of the poisonous umbelliferæ, our *Cicuta virosa*, or water-hemlock, comes nearer the ancient description than any other; and in reference to the use alleged to have been made of the ancient Κωνειον, it has the farther advantage of being generally considered

much more active poison than the common hemlock.

It may be right to add, however, that the *Conium maculatum* of modern botanists has been ascertained by Dr. Sibthorpe to grow abundantly in different parts of Greece. This eminent authority states he found it "on rubbish-heaps near Constantinople; not unfrequently in the Peloponesus; and most abundantly between Athens and Megara." It would have been very extraordinary if this species had not been a common plant in Greece, considering that it is abundant in every country in Europe. But I do not see how such a circumstance should be considered any proof that the ancient Κωνειον was our spotted hemlock, although some authors seem to look upon it as ample evidence of their identity*. It is not unworthy of remark, that the ancient term has been apparently lost in the modern Greek language, and that it bears no relation whatever to the modern name βρομοχοςτον, now applied, according to Sibthorpe, to the spotted hemlock.

The ancient accounts of the properties of Κωνειον as a poison, harmonize better than their botanical descriptions with what is known of the modern *Conium*. The fullest account is that of Nicander, in his Αλεξιφαρμακα; and subsequent writers have either followed him, or, where they have deviated, seem to have had in their eye the supposed properties of the Athenian state-poison. "Behold also," says he, "the baneful draught of Κωνειον; for this potion carries destruction to the powers of the mind (*literally*, to the head), bringing shady darkness; and makes the eyes roll. But staggering on their footsteps, and tripping on the streets, they creep on their hands. And mortal stifling seizes the upper part of the neck, and obstructs the narrow passage of the throat. The extremities grow cold; the strong vessels in the limbs contract; he ceases to draw in the thin air, like one fainting; and the soul visits Pluto." The Greek Κωνειον, according to this poetical version, rendered into brief prose, brings on obliteration of the mental faculties, dimness of sight, giddiness, staggering, stifling, coldness of the limbs, and death by asphyxia;—a view of its effects which differs little from the modern notions of the poisonous action of the spotted hemlock. But the poetical effusion of Nicander will apply equally well to many narcotics, and among others to various umbelliferous plants: it is a generic, though probably intended for a specific, description.

Nicander, who appears to have lived about 160 years before Christ, or, according to some, a century later, has evidently been followed by Diascorides, Pliny, and other subsequent authors, in his description; and where any deviation is observable, it has been in favour of Plato's account of the effects of the Athenian state-poison in the case of Socrates—this being either tacitly or expressly assumed to have been a preparation of Κωνειον. It seems needless, therefore, to prosecute the present branch of the inquiry by reference to other ancient narratives.

The result at which we must arrive is, that the Greek Κωνειον, so far as regards its effects, *may* be the modern *Conium maculatum*, but may be equally referred to various other plants; and that, if its botanical description by classical authors is to be allowed any weight at all, or, which amounts to the same thing, if we admit that the ancient naturalists did describe, and could describe, from nature, it must have been a totally different vegetable.

Turning, in the last place, to the Athenian state-poison, we find both historians and political authors who lived during the time it was in frequent use, assuming very much as a matter of course that this was the Greek Κωνειον; and subsequent writers identify it either with this plant, or with the Roman *cicuta*, which we have already seen to be the same with the Κωνειον.

Thus Xenophon, who died forty years after Socrates, and during whose lifetime the state-poison was the constant instrument of medical murder, speaking of the death of Theramenes, condemned for his political acts by the thirty tyrants, says, "and when he was condemned to die, and was drinking the Κωνειον, it is said he tossed away what remained, exclaiming, &c. In like manner the orator Lysias observes, in his oration against Eratosthenes, who had put his brother Polemarchus to death: "The thirty despatched to Polemarchus their customary order to drink Κωνειον." About the middle of the second century of the christian era, we find Diogenes Laertius following these authorities, when he mentions the death of Socrates. "Socrates imprisoned," observes he, "after a few days drank the Κωνειον, discoursing many beautiful and good things, which Plato has given in his Phædo." The same assumption is made by Pliny betwixt six and seven centuries later. "The *cicuta*," says he, "is a poison, abhorred because the instrument of public punishment among the Athenians, yet applicable to many purposes which are not to be omitted."

It is, nevertheless, not a little singular,

---

* Mérat et Delens, Dict. de Matière Méd. ii. 385.

that no mention is made of the Κωνειον as the state-poison of the Athenians by an author in natural history, who flourished at a time when the memory of the death of Socrates, Phocion, and many other eminent individuals, must have been fresh in the minds of all philosophers, and who nevertheless mentions both the plant and its poisonous qualies,—I mean Theophrastus. Theophrastus was born but twenty-eight years after the death of Socrates, namely, 371 years before Christ, and was Aristotle's successor in the Lyceum; yet he is altogether silent on the point. Every commentator has adduced the following remarkable passage from this author. "Thrasyas, the Mantinean, said, that by making use of the juices of the Κωνειον, the poppy, and such other things, he had discovered a substance which occasioned death easily and without pain, and so portable and minute, that the weight of a drachm was sufficient, and absolutely without a remedy, and capable of being preserved any length of time without alteration." It has been supposed by some that Theophrastus has here described the state-poison of the Athenians, but there is no evidence to this effect; and his silence on the point would rather tend to shew that the state-poison was a different substance.

Leaving these vague inquiries, however, let us see what has been said of the effects of the Athenian poison in those who were put to death with it; and we may then be able to settle, independently of either the assumptions or omissions of classic authors, whether it was the *κωνειον* of the Greek physicians or the *conium* of the moderns, or what else it may have been.

So far as I am aware, there is but one account extant of the effects of the Athenian state poison, but it is clear and precise. I allude to the familiar and pathetic narrative by Plato of the last hours of Socrates. Having first stated that the executioner told the philosopher that nothing could spared from the dose for a libation to the Gods, and that he was to walk about till he should feel his legs becoming heavy,—Plato goes on to say that Socrates drained the cup with tranquillity, upbraided his friends for their weakness when they burst into tears, and proceeded to walk as he had been directed. "At length," continues the narrative, "when he felt his limbs grow heavy, he lay down on his back; for so the man had told him to do. And at the same time the person who administered the poison went up to him, and examined for a little while his feet and legs, and then squeezing his foot strongly, asked whether he felt him do so? Socrates replied that he did not. After this, the man did the same to his legs, and proceeding upwards in this way showed us that he was cold and stiff. And he approached him and said to us, that when the effects of the poison should reach the heart, Socrates would depart. And now the parts about the lower belly were cold, when he uncovered himself (for he was covered up), and said, which were his last words: 'Crito, we owe Æsculapius a cock; pay the debt, and do not forget it.' 'It shall be done,' replied Crito; 'but consider whether you have any thing else to say.' Socrates answered not, but in a short time was convulsed. The man then uncovered him. His eyes were fixed; and when Crito observed this, he closed his eyelids and his mouth.

If this narrative be altered to a modern toxicological description, it is plain that the Athenian state-poison must be regarded as producing spasm and coldness of the limbs, gradually advancing to the internal parts, causing death eventually by acting either on the heart or respiration, and without affecting the functions of the mind even to the very last.

Such a view of its action is altogether at variance equally with the effects usually ascribed in recent times to the spotted hemlock, and with the phenomena presented in the experiments described in the present paper. It seems also not less at variance with the ideas entertained by the Greeks of the poisonous operation of their *κωνειον*, as will be apparent on comparing Plato's narrative with the general description of Nicander. And lastly, it seems to me incompatible with the ascertained effects of every poison whatsoever, which is known in modern times; for I think it will puzzle the most learned toxicologist to point out any poison which has the property of occasioning coldness and stiffness of the limbs, proceeding gradually upwards, and proving fatal without causing either pain or sopor.

There seems, then, no alternative but to conclude, either that the description of Plato—who, it must be remarked, was not present at the death of Socrates, as many imagine—is not a detail of facts, but an embellished narrative, written for effect; or that, although we are now acquainted probably with fifty times as many poisons as the ancient Athenians, and with many which are fifty times as active as any in their list, we have lost acquaintance with one with which the ancients were quite familiar, and which differs totally from every known poison in its action.*

* We have been obliged, for want of space, to omit several of the author's learned notes (chiefly corroborative of statements in the text), as well as the whole of his Appendix of select experiments.—Ed. Gaz.

ANEURISM BY ANASTOMOSIS;

With Operation and Remarks.

By John Russell, Esq.

Assistant-Surgeon to the 73rd Regiment.

To the Editor of the Medical Gazette.

Sir,

If you think the enclosed case of aneurism by anastomosis, from my note-book, worthy of a place in the Gazette, I will thank you to insert it.

Yours very truly,

John Russell.

7, Duke-street, Adelphi,
April 20, 1836.

In October, 1829, at Hobart Town, Mary Trotter, æt. 41, a laundress, applied to me with the following complaint: — She had two tumors, each about the size of a walnut, one at the extremity of the ring, the other of the little, finger of the left hand, extending along each finger to the middle, of a violet colour, spongy feel, and of a structure resembling a placenta. They shrunk under pressure, but recovered their size on its being removed; throbbed strongly, as did all the vessels of the arm; were excessively painful; and the whole frame was irritable. The radial and ulnar arteries were enlarged; the latter *tortuous;* the basilic vein had assumed the appearance so commonly seen in a varicose vein of the leg.

She stated that the disease had commenced *five* years before, on the tip of the ring finger, just under the nail, by a bleeding, without any previous symptom, while engaged in wringing clothes. At first, she observed a little speck, which ulcerated, cicatrized, and then gradually formed a little violet-coloured pulpy tumor, bleeding frequently, and sometimes freely. In *three* years more, a similar tumor appeared on the little finger of the same hand. The bleeding and inconvenience increased much. She applied twelve months before I saw her to a practitioner in the country, who put ligatures *round the fingers*, and cold astringent lotions, to restrain the hæmorrhage, which they had the effect of doing, but from *this time* she suffered excruciating pain: the menses were not affected by the hæmorrhage, but they have since ceased.

I recommended removal of the fingers at the metacarpal joints. She declined it; went about seeking other advice: some surgeons told her she must lose her arm; she returned to the country. In December following, she came back to me, and said she would submit to any thing, but the disease had now extended itself so far as to form *one* aneurismal tumor at the junction of the two fingers; the placenta-like appearance reached to the wrist; the arm was of an erythematous hue, to the elbow; the tumors had ulcerated and sloughed; and the carious phalanges protruded from the gangrenous fingers, which were enlarged and dreadfully painful; the little finger bent at right angles with the palm. The *pulsation* and *size* of the arteries and veins had considerably increased, even up to the *axilla*. The pain was aggravated by a depending position, by any mental emotion, and even by the act of respiration. Her constitution was fast sinking.

The case was seen by Dr. Macleod, Deputy Inspector-General of Hospitals, who agreed with me in the propriety of the operation I suggested. I wished to remove the disease, but to go as close to it as possible, in order to save a valuable portion of the hand; guided by what I believe may be considered a valuable principle in surgery—viz. if a disease not of a malignant nature be removed by the knife, its consequences will generally be subdued, or the parts secondarily affected will be restored to their natural condition. I therefore first tied the ulnar artery at the wrist, and then amputated the metacarpal bones of the ring and little finger, at the carpus, quickly and easily, being obliged to cut within the verge of the purple mass. Colonial Surgeon Scott, Mr. Bedford, and several other surgeons, were present.

To give some idea of the enlargement of the vessels leading to the diseased part, I may here mention, that while cutting on the ulnar artery, a superficial branch was divided, when I heard one of the gentlemen present say, "the ulnar is cut." It certainly spouted out as forcibly as that vessel might do under ordinary circumstances, and rendered it no very easy task to tie it. However, the ligature on it saved trouble afterwards, as it was only necessary to tie two small vessels.

The stump healed well. She was discharged on the 22d January, 1830.

In three years afterwards she called to thank me. All the morbid affections had long subsided, the vessels of the arm had resumed their natural appearance, and, with the assistance of the thumb and two fingers, she was enabled to follow her occupation of a laundress, scarcely missing the part removed.

This case, I believe, is unusual, as occurring in a person of advanced life, in a peculiar manner, presenting two similar tumors on the same hand. It is instructive, as, while it shews the efficacy of excision, as the only certain means of removing this disease, it illustrates Mr. Wardrop's observation, that a ligature on the artery leading to it may render that operation, otherwise impracticable, safe, although in this instance I applied one for a different purpose—viz. to enable me to shave the disease close. It shews the injurious consequence of a tight bandage around the member; and, lastly, that the secondary affections of surrounding parts are not to be dreaded.

THE PHOSPHATES IN URINE,

NOT HELD IN SOLUTION BY MURIATE OF AMMONIA.

To the Editor of the Medical Gazette.

Sir,

In replying to the communication contained in your journal of last week, I shall confine my remarks exclusively to the questions of how far, and under what circumstances, muriate of ammonia is to be looked upon as a solvent of phosphate of lime, or the mixed phosphates; what change, if any, the ammoniacal salt undergoes by mere heat; and lastly, why I adhere to the opinion that urine, under no conditions, as far as I have yet examined, undergoes by the effect of boiling a change capable of rendering it more acid; and I do this because neither facts nor arguments have been as yet brought forward, at all invalidating the accuracy of those experiments lately published, in which I have, I conceive, clearly shewn that the evolution of carbonic acid, in certain specimens of urine, and the deposition of the phosphatic salts, stand to each other in the relation of cause and effect.

In the first place your correspondent objects to that experiment in which I proved that a solution of muriate of ammonia, by boiling, does not evolve any thing capable of reddening turmeric paper, and insists upon the superior delicacy of litmus paper, previously reddened by a weak acid, as a test for alkalies. My own experiments have certainly not induced me to hold the reddened litmus in higher estimation than turmeric paper; besides, when litmus paper is reddened with a weak acid, such as the diluted acetic, frequently used for that purpose, it becomes open to an important objection, for the acid being volatile, it is easily driven off in all those experiments in which heat is necessarily employed as an agent. For example, in the case where the litmus paper thus reddened is suspended over a boiling fluid, such as the urine, the heat speedily volatilizes the acid, and the blue colour is, of course, restored to the paper, no alkali at all being set free. If reddened litmus paper be employed at all, it ought not to be reddened by a volatile, but by a very diluted fixed acid, such as the sulphuric or phosphoric acids. The muriate of ammonia employed in my experiments, was prepared by evaporating a mixture of muriatic acid and carbonate of ammonia, the latter being in excess, to dryness; the salt obtained is an acid salt; this is always the case, whether it be obtained by crystallization from its solution in water, or whether it be obtained by sublimation. If, then, a portion of reddened litmus paper be suspended over a boiling solution of muriate of ammonia, as prepared above, I maintain that the colour is not restored, neither is turmeric paper reddened; in fact, the vapour given off actually reddens blue litmus paper, when brisk ebullition is employed, as we might expect from the circumstance of the acid ammoniacal salt being carried up diffused through the aqueous vapor. If, however, we add a solution of ammonia to muriatic acid, in such proportions that the resulting fluid shall be neutral, then the application of heat will cause ammonia to be evolved, as shewn by the effect produced both on turmeric and reddened litmus paper; the fluid will also be found afterwards to have an acid re-action; in fact, that portion of ammonia not chemically combined with muriatic acid, and existing in the fluid merely in a state of admixture, is evolved, whilst the remaining portion is

chemically united to the muriatic acid, forming muriate of ammonia. Perhaps it is this circumstance which has led your correspondent to conclude that muriate of ammonia is capable of being decomposed by a boiling temperature, whereas it is clear that only the uncombined ammonia is evolved.

2dly. He invites me to repeat his experiments, as published in the Hospital Reports, in order to shew that the phosphatic salts can be precipitated by mere boiling, from a solution of muriate of ammonia, which solution contains a *notable portion* of free muriatic acid. It is exceedingly difficult to conceive the possibility of an earthy phosphate being precipitated by boiling, from a solution containing free muriatic acid; and still more difficult to understand how free ammonia can be evolved from such a solution, when we reflect, on the one hand, on the powerful solvent action which muriatic acid exerts over the earthy phosphates, and on the strong affinity which the same acid has for ammonia, on the other. Nevertheless, such is asserted to be the case. The only way, therefore, to determine the accuracy of this statement, apart from mere reasoning, which certainly is opposed to it, is by having recourse to direct experiment.

Exp. 1. Some phosphate of lime, recently precipitated and washed, was dissolved in diluted muriatic acid; to the solution ammonia was added, to throw down the phosphatic salt; diluted muriatic acid was then added, in sufficient quantity to render the fluid slightly acid, but still not in sufficient quantity to dissolve all the precipitated phosphate of lime; the whole was then filtered. The clear filtered fluid did not become turbid on boiling, neither did it evolve ammonia. Oxalate of ammonia, when added to it, caused a copious precipitate.

It is clear from this experiment, that if any muriatic acid existed, over and above that necessary for the formation of muriate of ammonia, it must have been in exceedingly small quantity; because sufficient was not added to dissolve all the phosphate of lime, and still this fluid was not rendered turbid by boiling; clearly confirming the position I before maintained—viz. that the earthy phosphate is not thrown down from its solution in muriate of ammonia, when any *notable* portion of free muriatic acid is present.

2. Another portion of phosphate of lime was precipitated from its muriatic solution, in the same way, by ammonia; but, in this case, only sufficient muriatic acid was afterwards added to render the fluid neutral; a considerable portion of phosphate of lime remained, by this means, undissolved: the whole was then filtered by boiling; the filtered fluid became turbid, and ammonia was evolved, the fluid becoming acid in its reaction. This experiment also demonstrates the truth of my former statement — viz. that it is only under *certain conditions* that the phosphatic salt is thrown down, by boiling, from its solution in muriate of ammonia, the condition being in this case that the fluid should be *neutral*, or at least not acid.

3. A portion of phosphate of lime was digested for some time in a cold saturated solution of muriate of ammonia; the whole was then filtered. The filtered fluid was acid, did not become turbid by boiling, neither did it evolve ammonia. Oxalate of ammonia caused a copious precipitate to fall; caustic ammonia and heat also produced a turbidity. This experiment confirms the truth of a former statement—viz. that the phosphatic salt was not thrown down from its solution in muriate of ammonia by boiling, when the ammoniacal salt was in excess; it is also directly confirmatory of the affirmation, that neutrality of the fluid, or at least a non-acid condition, is essential to the development of the phenomenon of the phosphatic deposition by boiling.

4. A portion of phosphate of lime in excess was digested in a weak solution of muriate of ammonia. The filtered fluid was acid, did not become turbid by heat, nor did it evolve ammonia, but was rendered turbid both by oxalate of ammonia and caustic ammonia, and heat. This experiment, then, not only confirms the preceding, indicating a necessity for a non-acid condition of the fluid, in order to admit of the precipitation of the phosphate, but also shows that phosphate of lime is not thrown down, even from a diluted solution of muriate of ammonia, by mere heat. Oxalate of ammonia was used in this experiment, to prove the existence of lime in the different solutions; caustic ammonia was employed in just sufficient quantity to render the fluids neutral.

To conclude, your correspondent "is at a loss to imagine how I could have deceived myself into the belief that the acidity of urine, affording a precipitate of phosphates by heat, is never increased by boiling." To this I reply, that my belief rests entirely on experiment; which, having been repeated sufficiently often, and with all possible caution, convinces me of the truth of such an assertion. Indeed, if the idea of superior acidity rested only upon the supposition that muriate of ammonia was decomposed, no experiment would have been necessary, previous investigations having quite satisfied me that the salt in question does not suffer decomposition at a boiling heat, or even at a temperature equal to its sublimation; but as other causes might have acted in effecting this change in the urine, I deemed it right to institute those experiments with tincture of litmus and ammonia already detailed in a previous number of your journal.

By giving insertion to these remarks, you will oblige,

Your obedient servant,
R. H. Brett, M.R.C.S.

Upper Sussex-street,
Old Kent Road, April 25, 1836.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'Alembert.

The English Flora of Sir James E. Smith. Vol. V. Part 2, comprising the Fungi. By the Rev. Miles J. Berkeley, M.A., F.L.S. 8vo.

The Principles of Descriptive and Physiological Botany. By the Rev. J. S. Henslow, M.A., F.L.S., &c., Professor of Botany in the University of Cambridge. 1 vol. 12mo.

A Compendium of the English Flora of Sir James E. Smith. Second Edition, with Additions and Corrections. By Dr. Hooker. 1 vol. 12mo.

We have long eagerly desired to see the concluding volume of Smith's English Flora, conscious how much such a work was needed, not only to embody the new species which had been discovered since the publication of Sowerby, and of Paxton's Flora of the Midland Counties of England, but that the whole might be arranged in accordance with the more accurate principles of classification developed by Fries, Nees von Esenbeck, and other continental botanists. To find in Britain one who had devoted sufficient attention to the subject to be competent to so difficult a task, is a circumstance upon which we may congratulate ourselves; for with the exception of Drs. Hooker and Greville, no British botanist has appeared to take any interest in the study of this intricate tribe of vegetables. That Dr. Hooker should have confided the preparation of this volume to the Rev. M. Berkeley was proof sufficient that he deemed him equal to the arduous duty; and the manner in which it is executed justifies his selection. With such a volume to consult, less excuse will exist for the neglect of this most singular and important tribe.

It is less our intention here to criticize the book (which, from its nature, does not admit of analysis, but only allows an opinion of it to be expressed), than to point out the reasons why medical men should bestow some attention on the productions of which it treats, since it will furnish them with a most valuable guide in their studies. Our surprise is great that so complete and accurate a work could be prepared in the time which it has occupied, especially by a person having other duties to engage him—considering how many intricate points required to be investigated and determined—so many volumes to be consulted, and so many references and citations to be made. We have compared most of the references to the plates of Bulliard, and Greville's Scottish Cryptogamic Flora, and found them extremely correct; indeed, we have noted but one inaccuracy—the reference, p. 12, genus Agaricus, sp. 20, A. melleus, to Bulliard, t. 370, should be t. 377. If any thing be wanting to render the work perfect, it is an index of the synonymes, which, though it would be a task of great labour to accomplish, would be eminently useful.

As instruction in botany now forms a part of the curriculum of medical education in England, we trust that the investigation of the habits and uses of fungi will be less neglected in future than it

has been hitherto. Indeed, it is a positive duty on the part of every medical man who wishes to render himself competent to the discharge of his professional responsibilities, by preparing himself for every emergency that may occur. How many accidents annually happen throughout Britain from the use of poisonous fungi, cautious as the people are of eating them! But independent of considerations which are of a practical nature, or have reference to medical jurisprudence, we are prepared to shew that in a physiological point of view they merit attention. We do not allude to such questions, as whether fungi may not be adduced as an example of equivocal generation, though we hold that they are no more proofs of such than a tree or a horse is, but rather wish to point out some of the circumstances which influence their development, structure, and properties. Any one who has examined the beautiful plates of Dr. Greville's Scottish Cryptogamic Flora, must have observed that every genus has a definite locality for, and peculiar arrangement of, its reproductive particles. In fact, each genus has as fixed a character in respect to the reproductive organs, as any of the more highly organized vegetables, such as a rose or a pear-tree. The sporidia, or reproductive particles of fungi, are, however, far more numerous than the seeds of any flowering plant, while, possibly, they can retain a power of development as long: being exceedingly small, in most cases they escape the observation of the common eye, and being wafted by the wind, they are conveyed to almost every spot where any organized matter exists, whether it be living or dead. That they do not develop themselves on every spot where they alight, even though there be the proper pabulum for their growth, is precisely one of those circumstances in their history which invites the attention of every physiologist. Fungi are eminently meteoric, or are developed only under certain atmospheric conditions; they furnish, therefore, criteria of alterations in the air, of very great importance. Almost every person knows that the common mushrooms are more abundant in some seasons than others; and it is stated in Sowerby's Fungi, when speaking of some species found in Epping or Hainault Forest, that occasionally twenty years may elapse between the periods when it is to be found, and then it is discovered near the same spot as before. The inference from this is, in our view, that the sporidia were there during the whole interval, but were dormant, not being called into action till a recurrence of the same atmospheric state.

In a former paper (Review of Watson's Geography of British Plants, Med. Gazette, Feb. 27, 1836) we quoted from a Memoir on Medical Topography, in which it is stated that "an unusual growth of fungi has preceded the most destructive scourges of mankind." After violent commotions of the atmosphere, also, not only are they frequently very abundant, but then new or rare species may be met with,—witness *Agaricus polystictus*, found by Mr. Berkeley after a fortnight's very stormy weather (op. cit. p. 9.)

The geographical distribution of some fungi is very extensive: we learn from Sir W. Jones that the Boletus igniarius occurs in India, and is applied to similar uses as in Europe; and Mr. Tytler, in his remarks on the climate of Mullye, at the foot of the mountains of Nepaul (Trans. of Medical and Physical Society of Calcutta, vol. iv. p. 372) says, "The last thing I have to mention may serve to illustrate the nature of the climate. Small mushrooms grow in every corner that is the least neglected, even in the most frequented rooms: left to themselves they would attain the height of about two inches, with a top rather larger than a shilling; but they are generally discovered and brushed away before they reach maturity." We have no doubt but that this is the same as the Agaricus domesticus (Bolton, t. 26), which appears in our own country under similar circumstances, or, as Fries says, "*Jove pluvio.*"

A great and interesting peculiarity of fungi, is, that apparently the same species is wholesome or poisonous, according to the country, locality, or season, in which it grows. The peasantry of Russia, and also a portion of that of Germany, Switzerland, and Savoy, live on fungi during a great portion of the year. Some, which in other countries are deemed poisonous, are by them eagerly collected and preserved for future use. It has been thought that in these climates their poisonous qualities were not so fully developed, or that the salting and vinegar, or the application of heat in cooking, deprived them of

their noxious properties. It is probable, however, that these people observe great discrimination, not only in collecting the proper sort, but in ascertaining that they are in a proper state. It may be asserted that scarcely any fungus is decidedly poisonous when in a young state, but almost all, even the *Agaricus campestris*, become so when hastening to decay.

A principle similar to, if not identical with, hydrocyanic acid (many have a smell of prussic acid, *Ag. cerasinus*, &c.) is formed in them when old, which is one source of danger (and for this the best antidote is about 20 minims of caustic ammonia in gruel—see Wolff, in Rust's Magazine, vol. xxxvi.). Many, however, are acrid, and excite inflammation of the coats of the stomach, (which requires venesection,) as well as possess a narcotic power. Most of those with a milky juice are acrid; but many lose their acridity by the application of heat: such as *Agaricus piperatus*, Scop.; or when preserved with salt and vinegar, such as *Agaricus torminosus* (Schaeff). Those which grow in open pastures are much safer than those found in woods; a fact known to the ancients.

> —— Pratensibus optima fungis
> Natura est: aliis male creditur.
> HOR. SAT. Lib. ii. Sat. iv. l. 20.

That the poor of our own country, from their ignorance respecting natural productions generally, and fungi especially, lose a nourishing article of food, and even a luxury, is easily shown. Not fewer than 26 different species of fungi, growing in Britain, are fit for food; yet, if we except about three species, none are ever brought to market, or preserved for their own use. The nourishing power of fungi is not only demonstrated by the usages of the Russian and German peasantry, who, though we courteously designate them *boors*, as the Romans called all foreigners *barbari*, certainly surpass us in their observation of the qualities of natural objects, and the profitable uses to which they may be applied. Chemical analysis exhibits their approximation to animal matter, and in many, examined by Vauquelin, osmazome was found. But there is no hope of this fruitful field being turned to a beneficial account by our peasantry, unless medical men and clergymen, located in every part of the country, first become acquainted with the wholesome species. By way of facilitating the acquisition of a knowledge of this subject, Mr. Berkeley has commenced the publication of Dried Specimens of British Fungi, described in the volume now noticed, to be continued in half-yearly fasciculi.

It is the peculiar privilege of the rising generation of British botanists, to have elementary works on the science prepared for them by individuals eminent in their rank as naturalists. The meagre works which were put into the hands of students in former days, have been dispossessed of their place in the library of the tyro, by the more scientific Introduction of Dr. Lindley; and now, in smaller compass, but equally philosophical in its arrangement and matter, the volume from the pen of Professor Henslow will form a manual calculated to diffuse a knowledge of botany on sound principles. While it is extremely concise, it is remarkably clear: no branch of the subject has been omitted, yet each is intelligibly treated—some, indeed, more so than in any work we have seen: the doctrine of the spiral arrangement of leaves is elucidated in a more perspicuous manner than in the original work of Braun, Martin's, or Alph. Decandolle; and as it is the most important discovery in vegetable physics which late years have made known, Professor Henslow's explanation of it is extremely valuable. The index is made to serve the purpose of a glossary, which is a great convenience and saving of time. Hitherto, if any introductions to botany were cheap, they were at the same time bad, being the productions of hacks and journeymen in the science. But in this instance, cheapness and excellence are combined.

The peculiarities of the new edition of Smith's Compendium, by Dr. Hooker, are, that it embodies the most recent discoveries of new species, even some made in the course of last year; and not only refers each genus to its place in the system of Jussieu, but points out the groups that are natural, and furnishes short notices occasionally, of the general habits and qualities of the more extensive natural orders. This will tend to make known to those who have hitherto used only the artificial system, the superior merits of the natural, and gradually lead to its more general adoption, as the only one worthy of permanent study and attention.

MEDICAL GAZETTE.

Saturday, April 30, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

MEETINGS IN THE COUNTIES,

TO REFORM THE PRESENT POOR-LAW.

APATHETIC and indifferent as the members of our profession generally are, in matters relating to their common advantage, it is satisfactory to observe the stir which is now taking place amongst them—roused and goaded, we should say, into activity by the iniquitous burdens attempted to be imposed upon them. For this they are indebted to the vile new Poor-law—that measure so universally reprobated, but which, in this instance, we are persuaded has worked beneficially. There is no evil pure and unmixed; and, no thanks to our legislators, the new enactment, by pressing with intolerable severity on the already overburdened practitioners who minister to the medical wants of the poorer classes of the community, has done this good,—it has drawn the members of the profession, throughout the country, more closely together, and promises to effect a firm bond of union amongst them, which would otherwise, perhaps, not be thought of.

The practitioners of the counties of Warwick and Worcester, it will be seen by our journal of this day, have had their meetings, and adopted measures which we trust will be followed up with energy. The deputations ought, in every case, to be most cautiously selected; men of high ability, weight, and influence, but, above all, conspicuous for their firmness and active zeal in the cause, should compose those important bodies appointed to deal with the Minister. Members of Parliament, truly *honourable* men, should by all means be secured as supporters, both in and out of the House. But we need scarcely proceed with our suggestions; other meetings, and associations to be formed in other counties, cannot do better than imitate the example so ably set before them, particularly by the practitioners of Buckinghamshire.

We were glad to find that both at the Worcester and Warwick meetings the conduct of the Buckingham memorialists was duly appreciated. The good effect and example of the numerous signatures appended to the remonstrance of the latter county, we feel confident will not be suffered to be lost. It was this document, supported as it was by a most efficient deputation, that first procured a hearing for the grievances borne by the mass of the practitioners of England: until Buckinghamshire moved in this effectual manner, the functionaries of the Poor-Law Commission had it all their own way; the cry of the profession was cushioned and nearly stifled.

Very far, however, are we from being sanguine as to the results, should the zeal of the remonstrants in any quarter become relaxed. The measures already adopted by the midland counties must be not only imitated extensively throughout the country at large, but pushed by the prime movers till the main object be fully accomplished. The officials of the existing law, we observe, pursue their system as before, unaltered: advertisements for *tenders* are inserted daily in the newspapers, nor can we see any thing in their offensive form calculated to impress us with the idea that correction has yet reached the executive in any of the districts.

A very powerful effect, no doubt, will result from the grand aggregate meeting of the profession, which it is intended shall take place at Manchester in the autumn. But we fear the date is too distant to reap all the benefit that might be expected to result from so important a

step. Parliament will have been prorogued, or wearied out with other business by that time, and any influence to be exerted in that quarter can only be efficient in the subsequent session. At a much earlier date the provincial associations will have met, and we trust so valuable an opportunity of evincing the interest taken in this subject by all the distinguished practitioners of the provinces, will not be suffered to escape. Meantime, let the work of co-operation in the separate counties go vigorously forward: nothing can be gained without a display of feeling. Petitions, memorials, remonstrances, and deputations, should be employed to state the just complaints of the profession, both to Parliament and at the Home Office. Without this, and unless it be promptly done, the fruits of all the late laudable proceedings on the part of the friends of the profession, will have perished, and the cause of justice and humanity may be despaired of.

MEDICAL EVIDENCE ON A TRIAL FOR MANSLAUGHTER.

In another part of the present number will be found a report of an interesting trial, at which much medical evidence was adduced. Two Professors of the Edinburgh School were summoned to give their testimony on the occasion, but, as will be seen, there was so much apparent contradiction in the opinions elicited from those learned persons, that they perfectly neutralized each other: at least such was the impression of the judge who tried the case, and left it ultimately to the plain common sense of the jury. The cause of this disagreeable occurrence (for such we must account it, where high medical authorities appeared before the public giving opinions of so contrary a nature), may, we think, be traced to the fact, that one of the parties in question was summoned on behalf of the prisoner, and the prisoner's counsel good took care to keep him to the abstract point—whether such and such fractures might not have resulted from falls, independently of injuries actually inflicted. The decision of the jury was right. The moral and circumstantial evidence was complete. The blows inflicted with the poker were not denied, and whether they left ecchymoses or not, it would be quite too large a draught on our faith to suppose that the fractures which were produced, anomalous as they were allowed to be on the supposition most favourable to the prisoner, were after all not owing to the application of the heavy instrument used, but the mere result of accident.

COLLEGE OF PHYSICIANS.

At the *conversazione* on Monday evening last, when Dr. Turner presided, a very interesting paper, by Dr. Mower, was read, on the subject of the habits and peculiarities of the seamen of various nations, as evinced by their conduct while under treatment on board the hospital ship, the Dreadnought. The author being visiting physician to that establishment, has had ample opportunity of witnessing the facts which he describes. We shall publish the paper next week.

UNIVERSITY OF BERLIN.

MEDICAL ARRANGEMENTS.

Many readers, we doubt not, will be glad to know the order of the courses pursued by the medical faculty, at Berlin. The following are the arrangements for the summer semester, only begun on Monday last, the 25th inst.

Ordinary Professors.

Dr. John Mueller, Dean, will lecture *publicly** on Saturdays, from 9 to

* It is well known, that in the German Universities, the *public* courses are little more than mere matter of form; the *private* constituting the main business of the Professors, from which, in fact, they derive their chief emolument.

10, on the physiology of generation. The *private* course will comprehend, 1. special human physiology, illustrated by experiments and demonstrations on animals: time, five days in the week, from 9 to 10; 2. comparative anatomy, Monday, Tuesday, Thursday, and Friday, from 8 to 9; 3. pathological anatomy, Mondays, Wednesdays, and Saturdays, from 6 to 7, P.M.

Dr. E. D. A. Bartels, publicly, on the aphorisms of Hippocrates, Thursday, from 4 to 5. Privately, his medical clinique, in La Charité, from 11 to 1, daily.

Dr. W. H. Busch, publicly, on the diseases of the female organs, Wednesdays, at 4. Privately, his obstetric clinique in the University Lying-in Hospital, Mondays, Tuesdays, Thursdays, and Fridays, at 4. *Privatissime*, he gives instructions in practical midwifery.

Dr. C. F. von Graefe, on surgery, Mondays, Tuesdays, Thursdays, and Fridays, at 3. On clinical and eye surgery at the University Hospital, from 2 to 3, as usual.

Dr. J. F. C. Hecker, publicly, on the encyclopædia and methodology, Wednesday and Saturday, at 1. Privately, on the modern history of medicine, Monday and Thursday, at 4: historical pathology, Tuesday and Friday, at 4: and on special therapeutics, every day, from 9 to 10.

Dr. J. Horkel, privately, on general physiology, daily, from 1 to 2.

Dr. E. Horn, publicly, pathology, with general and special therapeutics, Wednesday and Saturday, at 8. Privately, special pathology, Monday, Tuesday, Thursday and Friday, at 8.

Dr. C. W. Hufeland, privately, practical medicine in the University Policlinial Hospital, 1 to 2 daily, as his health may permit.

Dr. Fr. Hufeland, publicly, on pathogeny, Wednesday and Saturday, at 9. Privately, on Semiotics, Tuesday, Thursday, and Friday, at 10: and on special therapeutics, the elementary part, daily, at 1.

Dr. J. C. Juengken, publicly, on the diseases of the organs of hearing, Thursday and Friday, at 4. Privately, on general and special surgery, Monday, Tuesday, Wednesday, and Saturday, at 4: on aciurgy, or the practice of surgical operations, with Dr. Kluge, daily, from 6 to 8, A.M. Demonstrations on the dead body, daily, from 6 to 8 in the evening. Eye clinique, 5 days in the week, at 9.

Dr. H. F. Link, publicly, on the medicinal and poisonous properties of vegetables generally; Saturdays, at 8, with botanical excursions in the afternoon. Privately, on botany, theoretical and practical, with demonstrations, daily, from 7 to 8. On natural history, from 8 to 9, on five days in the week.

Dr. H. Osann, publicly, on the medicinal waters of Germany, Wednesday and Saturday, at 9. Privately, practice of medicine in the Royal Polyclinic of the University, at 1 daily. On materia medica, after Hufeland's method, daily, from 5 to 6.

Dr. J. N. Rust, publicly, on some parts of surgery, 12 to 1, daily. Privately, the clinique in La Charité, from 10 to 11½ as usual.

Dr. F. Schlemm, publicly, on the organs of the senses, Mondays and Tuesdays, at 11. Privately, on osteology, Monday, Tuesday, and Thursday, at 12; and on surgical anatomy, the first five days of the week, at 7 A.M.

Dr. C. H. Schultz, publicly, on general physiology and pathology, Saturdays, at 8. Privately, medical botany and the physiology of plants, with microscopical demonstrations and excursions, daily, at 10; on medical natural history, five days, at 7; on human physiology, with experiments on animals, five days, at 8.

Dr. W. Wagner, publicly, on medical police, Wednesdays and Saturdays, at 7 A.M. Privately, general pathology and therapeutics, Mondays, Tuesdays, Thursdays, and Fridays, at 7 A.M.; on forensic medicine, Mondays, Tuesdays, and Thursdays, at 3; and on the practice of forensic medicine, with demonstrations, as usual, on Wednesdays and Saturdays, from 6 to 7 P.M.

Extraordinary Professors.

Dr. J. L. Casper, privately, on forensic medicine, for students of law and medicine, with practical exercises in the art of drawing up reports, consultations, &c. Tuesday, Wednesday, and Friday, at 9; on the art of prescribing, Mondays and Thursdays, at 12; with exercises on practical pharmacy, as usual.

Dr. J. F. Dieffenbach, publicly, on hernias, Saturdays, at 9. Privately, general and special surgery, five days in the week, at 9; aciurgy, time not yet fixed.

Dr. C. G. Ehrenberg, publicly, on the comparative physiology of infusoria, entozoa, and other animals not easily observed, on Saturday, from 12 to 1½.

Dr. R. Froriep, privately, general and special surgery, daily from 5 to 6 in the afternoon; on surgical anatomy, daily at 7 in the morning.

Dr. C. F. Kluge, publicly, on luxations, Monday and Tuesday, at 11. Privately, on the art of bandaging, Wednesday and Saturday, at 10; on theoretical and practical midwifery, Thursday and Friday, from 3 to 5; on acirgy, with Professor Jüngken, daily at 6 A.M.; the syphilitic clinique of La Charité, on Wednesday and Saturday, at 8; demonstrations and operations on the dead body, from 6 to 8 in the evening; obstetrical clinique in La Charité, on Thursdays and Fridays, at 5.

Dr. F. G. Kranichfeld, publicly, medical methodology, Tuesday and Thursday, at 9. Privately, on hygiène, or the preservation of health, Monday, Tuesday, Thursday, and Friday, at 5; on the special therapeutics of the human eye, with clinique and operations, daily at 3.

Dr. G. C. Reich, publicly, on diseases of growth, Saturday, at 1. Privately, pathology and special therapeutics, from 8 to 10.

Dr. L. F. Truestedt, privately, medical chirurgical practice in the ambulatory clinique belonging to the University, every day at 1.

Dr. E. Wolff, privately, clinique in La Charité, daily at 8.

Privatim Docentes.

We can only give the names and subjects of this class of lecturers; they are as follows:—

Dr. Angelstein, eye surgery; Dr. Ascherson, general surgery; Dr. Barez, diseases of children; Dr. Dann, pathology and therapeutics; Dr. E. A. Graefe, surgery; Dr. Ideler, anthropology, and diseases of the mind; Dr. Isensee, pathology, pharmacology, and pharmacy; Dr. C. G. Mitscherlich, materia medica; Dr. Nicolai, medical police, and general pathology; Dr. Oppert, syphilitic diseases, and general therapeutics; Dr. Phœbus, pathological anatomy; Dr. Reckleben, veterinary medicine; Dr. Romberg, diseases of the nerves, diagnosis, and clinical demonstrations; Dr. Troschel, helcology, surgery, diseases of the teeth; and Dr. Wilde, midwifery and obstetrical operations.

Among the professors, ordinary and extraordinary, belonging to the

Philosophical Faculty,

we may notice the following: — Dr. P. Erman, on electricity, magnetism, and meteorological atmosphærology; Dr. Kunth, on botany; Dr. Lichtenstein, ornithology and general zoology; Dr. E. Mitscherlich, experimental chemistry and zoo-chemistry; Dr. Rose, analytical chemistry and inorganic pharmacy; Dr. Weiss, crystallography and practical mineralogy; Dr. T. Hartig, entomology; Dr. Turte, physics for students of medicine and surgery; and *privatim docens*, Dr. Burmeister, on medical natural history.

LECTURES

ON

DISEASES OF THE RECTUM;

Delivered in the Theatre of St. George's Hospital,

By Sir Benjamin Brodie, Bart.

[Concluded from p. 490 of the preceding Volume.]

TREATMENT OF FISTULA IN ANO.

As I explained to you, in the last lecture, the operation for the cure of a fistulous sinus connected with the rectum has a double object. *First*, the sinus is to be laid open into the intestine, so that there may be no recess in which matter may lie and lodge. *Secondly*, the fibres of the sphincter muscle, which are implicated in the disease, and the action of which tends to prevent the healing of the sinus, are to be divided. These objects may be attained in different ways.

1. The fistula may be laid open by means of caustic. I have seen this method practised, and I have practised it myself. You introduce a probe into the external orifice, and having passed it into the gut at the upper extremity of the fistula, you bend it in such a manner as that one extremity should project at the anus. The parts, which lie over the probe, are then to be destroyed by the application of a conical piece of the caustic potash (*potassa fusa*). The caustic should be fresh made, and of the best quality; and the neighbouring parts, while the caustic continues to operate, are to be defended by washing them with vinegar, or the *liquor plumbi subacetatis*. This operation succeeds well enough in cases of small fistulæ, which are superficially situated; but in every

other case it is a most severe and painful proceeding, which I do not recommend you to adopt.

2. The *fistula* may be laid open by the pressure of a ligature.

This method has been generally resorted to by empirics, whose object it was to catch those patients who were too timid to submit to the operation by a cutting instrument. However, it has been recommended also by some experienced surgeons, and there is a paper on the subject in Desault's surgical works. Desault employed, as a ligature, a long leaden wire. By means of an apparatus especially contrived for this purpose, he introduced one extremity of the ligature at the external orifice of the fistula; then, at the upper extremity of it, he made it penetrate the gut, and afterwards brought it out again at the anus. The two extremities of the ligature were afterwards made to pass through a silver canula, and drawn tighter on it daily, in the same manner as after the operation for polypus of the uterus, and with the same intention—namely, that the parts included in the ligature should be divided by ulceration. I have performed the operation in this manner several times formerly, but not of late years, as I found it to be liable to great objections. It gave the patient, on the whole, much more pain than he would have had from a cutting instrument: only one sinus could be laid open at a time, and if there were several sinuses the cure was very tedious, because the operation was to be repeated for each of them. If any considerable portion of the sphincter muscle was included in the ligature, the pressure of it was scarcely sufficient to produce ulceration; so that it was at last necessary to finish the operation by the knife. In short, I could not find that this method had any advantages over the common method of operating, and it had many disadvantages. If you think it worth while to know more of the subject than what I have now stated, you may refer to the observations which have been published by Desault, and among which you will find a particular account of the instruments which he was accustomed to use when he operated in this manner.

3. No surgeon who has been much engaged in practice, can doubt that the best method of laying open a *fistula in ani,* is by means of a cutting instrument. In some cases, a pair of narrow, straight, probe-pointed, knife-edged scissars, will answer the intended purpose better than any thing else. Thus, if there be a fistula with the external orifice close to the verge of the anus, and not of a very large size, and terminating immediately above the sphincter muscle, you have only to introduce one blade of the scissars, such as I have described, into the fistula, and the other blade into the rectum, and then divide the intermediate parts. If the fistula has an internal orifice communicating with the gut, you should take care that this is included in the incision. The advantage of using the scissars is that the operation is attended with comparatively little pain. Unfortunately it is applicable to only a limited number of cases.

In general you will find it most expedient to lay open the fistula with a bistoury. You should be provided with, 1st, a probe; 2dly, a silver director (I say silver, because it ought to be flexible); 3dly, a common sharp-pointed bistoury, slightly curved, the edge being on the concave side; 4thly, a probe-pointed bistoury, slightly curved also (commonly called a Pott's bistoury); and 5thly, a straight probe-pointed bistoury. Some, or even all, of these instruments may be required, according to circumstances.

The patient may be placed leaning over a table, with his back to the light, or he may lie on one side, at the edge of a bed or sofa, with his thighs bent forward on the pelvis. In either position, the nates must be held apart by an assistant. The fore-finger of one hand being introduced into the rectum, you are, with the other hand, to pass the probe into the *fistula*, and then ascertain the following circumstances:—1. Whether there be already an opening into the gut, and where it is situated. 2. The extent of the fistula upwards. 3. Whether there be more than one sinus, and if so, in what direction the several sinuses extend. It is of great importance that you should have an exact knowledge on all these points, before you proceed further.

Let us suppose, first, that there is a single sinus, having an external opening near the anus, and an internal opening communicating with the rectum. It is quite necessary that the latter should be included in the incision. If the internal opening be at the upper extremity of the sinus, the operation is simple enough: you introduce the fore finger of one hand into the rectum, and with the other hand you direct the curved probe-pointed bistoury through the external opening into the sinus, and afterwards through the internal opening into the rectum; then, keeping the probe-point in contact with the fore-finger, you draw the instrument downwards, dividing all the parts below it.

If the internal opening be any where in the middle part of the sinus, you proceed in the same manner; but a second incision is then necessary, to lay open the upper extremity of the sinus. The probe-point of the bistoury must be made to penetrate

the tunics of the rectum, before this second incision is made.

If the sinus has no communication with the rectum, the tunics of the latter must be penetrated as near as possible to the upper extremity of the sinus, the incision being made afterwards in the manner which has been just explained.

This is the operation with Pott's bistoury. But there is another very convenient method of proceeding with a director and a sharp-pointed bistoury. You introduce the director into the sinus, and afterwards into the rectum, either through the internal opening, if one already exists, or by making it gradually penetrate through its tunics, if no internal opening can be discovered. Then you bend the director so as to make one extremity of it project through the anus, and divide the soft parts which lie over it, by passing the sharp pointed bistoury along its groove.

If there be several sinuses, the whole of them are to be divided in the same manner. If any one of them be left undivided, it is most probable that the operation will prove to be unsuccessful.

In many instances you will find it to be expedient to do more than merely lay open the sinuses. I have already explained that the continued action of the sphincter muscle seems to be one principal cause preventing the sinus or sinuses from healing, without an operation. The same cause will often render the cure difficult, even after the sinuses are laid open. You may get rid of this difficulty in the following manner:—After the first incision has been made, turn the edge of the bistoury in the other direction—that is, outwards—and divide the fibres of the sphincter so as to set the muscle completely at liberty. You may, if you please, do this with the bistoury which you employed in the first part of the operation, but it is more conveniently accomplished with the straight bistoury, or with one which is slightly convex on its cutting edge. The advantage of the division of the sphincter is not merely theoretical. There are few cases in which it will not greatly facilitate the ultimate cure; preventing the burrowing of matter and the formation of fresh sinuses, and rendering the subsequent dressings more easy to the surgeon, and less painful to the patient. It is, however, to the more complicated cases of fistula, that the division of the sphincter is especially applicable; as, for example, where the sinus is of unusual extent, or where there are several sinuses, or where you are not certain that you have been able to detect the whole of them, or where the neighbouring soft parts are extensively indurated. It is quite a mistake to suppose that there is any well-founded objection to even the most free division of the sphincter. It scarcely interferes with the retention of the fæces, (except they are actually liquid) even in the first instance, and the muscle never fails to become perfectly united, and to perform its functions as well as ever afterwards: nor have I ever known any hæmorrhage to arise, which was not readily commanded by a dossil of lint introduced into the wound, and the pressure of the finger continued for a short space of time. If there be any considerable bleeding vessel, it is not difficult to secure it with the tenaculum and ligature, but this is seldom necessary.

One of the most troublesome parts of the operation, in some instances, is the introduction of the probe point of the bistoury through the gut, where the fistula has no internal opening, or where that opening is not situated at its superior extremity. Mr. Savigny invented a bistoury which was intended to meet this difficulty, There was a second blade fixed to the side of the other, having a sharp point, which might be made to project by the pressure of the finger, so as at once to penetrate the soft parts wherever the opening was required, the sharp point being immediately withdrawn as soon as its purpose was accomplished. This contrivance is sometimes useful, but there is a material objection to it in many cases. The double blade increases the bulk of the bistoury, so that it is too large to be employed where the fistula is of very narrow diameter.

Some eminent French surgeons have used a sort of scoop, or gorget, made of box-wood, which was intended to be introduced into the rectum instead of the forefinger. The only purpose which it answers, (as far as I know) is that of saving the surgeon's forefinger: but in using it, you lose another advantage, namely, that of the sense of touch; and in my own practice, I have found that I could complete the operation better with my forefinger than with the wooden gorget.

These, however, are only slight differences in the mechanical part of the operation, involving no difference in the principle on which it is performed.

When the sinus, or sinuses, are completely laid open, the wound is to be dressed, by laying a piece of lint between the cut edges. Observe that the only object of this dressing is to prevent the cohesion of the opposite surfaces, and that you cannot dress them too lightly. If you cram the sinuses as full as possible of lint, you give the patient great pain, and you prevent the free escape of the purulent discharge, which will, in consequence, burrow, and make fresh sinuses. If opium agrees with the patient, it is worth while,

immediately after the operation, to give a few drops of laudanum, with a view, not to relieve pain, but to occasion costiveness, so that the dressings may remain undisturbed for two or three days. After this, a gentle aperient may be administered, which will prevent the ill effects of a too long-continued constipation, and, at the same time, bring away the first dressings. It is a false notion to suppose that the immediate re-introduction of the dressings is a matter of importance. On the contrary, it is much better to apply merely a poultice to the external parts for three or four days, until the first inflammation, consequent on the operation, has subsided. After this, you may dress the sinuses daily, either with dry lint, or with lint spread with some stimulating ointment, or soaked in a stimulating lotion. But still observe the rule which I have already laid down, of dressing the parts as lightly as possible. If you do otherwise, each dressing is almost, or quite, as painful as the original operation; and, owing to the confinement of the discharge, the old sinuses become extended, or fresh sinuses are formed. I am convinced that it is chiefly in consequence of the use of too much lint in dressing, that it so frequently happens that further operations are found to be wanted before the patient's cure is completed. The daily dressing should be repeated until the cut surfaces are cicatrized, but no longer. The cicatrization of the bottom of the sinus will be completed better without the dressing than with it. The lint is, in fact, like a seton, keeping up ulceration and suppuration, and after it has done what is wanted, in preventing the adhesion of the surfaces nearest to the anus and rectum, the sooner it is dispensed with the better.

After the sinuses are healed, there is always a sort of fissure or chink left by the side of the anus, which gradually fills up. If the sinus has been deep, this chink will be deep in proportion, and then an inconvenience will follow, which is of little consequence, but of which you should inform your patient, as otherwise he may think that the disease is not cured, though it is so in reality. The mucus of the rectum, sometimes stained with the fæces, will flow through it, and stain the linen. But this is only temporary; the chink, however deep, will gradually close, and the mucus will ultimately be retained as well as ever. If the patient be anxious on the subject of this mucous discharge, you may easily set his mind at ease by pointing out to him that it is not purulent, but that it dries and becomes stiff on his linen, as if it were starch.

In a few cases, in spite of all your care, you will not discover all the sinuses in the first instance; and if the wound does not heal as under ordinary circumstances, you will generally have reason to suspect that a sinus remains undivided. Under these circumstances, you must examine the parts again and again, until you discover this other sinus, which must then be laid open like the former ones. Such an undetected sinus is occasionally no small annoyance both to the patient and to the surgeon. I attended a lady who suffered from a complication of several sinuses near the rectum. I laid open all that I could discover, and the healing process seemed to be going on favourably; but after a considerable lapse of time, it was not completed: and all this time she complained of uneasy sensations, which I could not well explain. After repeated examinations, I discovered a sinus high up, not more than an inch in length, which seemed to be involved in the *levator ani* muscle. I laid it open, and she was immediately relieved, and in a very short time her cure was completed.

It very rarely happens that any bad consequences supervene on this operation. We can scarcely reckon hæmorrhage among them, as we can always command it. In seasons when erysipelas has prevailed, I have known it sometimes begin at the wound, extend over the nates, and afterwards over the neighbouring parts, and, of course, erysipelas is always attended with a certain degree of hazard. In a very few cases erysipelas appears to extend up the mucous membrane of the rectum into the other parts of the intestine; and this is a most formidable disease indeed. The symptoms are very peculiar, and, as far as I know, are not described by writers. The pulse becomes very rapid, and at the same time, weak; then it is irregular, and intermitting. The abdomen is tympanitic, in consequence of the intestines being distended with air; hiccough takes place; there is a great prostration of strength; and the patient often dies in the course of three or four days, sometimes sooner. A lady was under my care, on account of a very complicated fistula, with a great number of sinuses; it was one of the worst cases of the kind which I ever met with. After the operation, however, the sinuses gradually healed, and at the end of three or four months (or perhaps the period was longer, for I have no notes of the case) she was so nearly well, that the day was fixed for her leaving London. At this period she had a severe rigor, and fell into a state of collapse. Erysipelas appeared at the anus, and extended a little way on the nates; but it was evident that it extended chiefly up the inner membrane of the intestines. The symptoms, which I have already described,

shewed themselves in a more intense form than in any other case which has fallen under my observation. She never completely recovered from the state of collapse which immediately followed the rigor, and she died in less than forty-eight hours. This internal erysipelas, however, is not necessarily fatal. I have known more than one case in which it manifestly occurred, but without the usual prostration of strength, and the patients recovered. When I have met with a case of this kind, I could never entertain a doubt as to the medical treatment which should be employed. It is sufficiently indicated by the symptoms; and for the most part the great failure of the vital powers demands the free exhibition of cordials and stimulants.

I stated in a former lecture, that a large abscess is sometimes formed high up by the side of the rectum, and above the sphincter muscle. When the existence of such an abscess is ascertained, you ought without delay to puncture it, otherwise not only will the patient have to undergo a great deal of unnecessary pain, but the abscess will extend itself in the pelvis until it attains an enormous size. You must ascertain the situation of the abscess, by observing to what part the pain is referred, and by examining the rectum with the finger. Then introduce a lancet through the external skin by the side of the anus, in the direction of the abscess, until the matter flows. Frequently the abscess is at such a depth that the lancet does not reach it until nearly the whole of the blade has penetrated the soft parts; and sometimes an ordinary lancet is scarcely of sufficient length to accomplish what is wanted. You are then to introduce a probe-pointed bistoury through the opening thus made, and divide the rectum at the lower part of the abscess, carrying the incision downwards, so as to include the sphincter ani muscle, as you would in an ordinary case of fistula. These incisions make a free opening into the abscess, which is immediately emptied of its contents. The wound is then to be dressed in the ordinary way, and nothing more is wanted. It is quite unnecessary, in these cases, to lay the whole abscess open into the rectum; the free division of it at the lower part is sufficient; and if the incision were to extend further, it might give rise to a dangerous hæmorrhage from large blood-vessels beyond the reach of the finger.

I have met with abscesses, such as I have now described, containing from half a pint to a pint of matter. I have had no opportunities of dissection, so as to ascertain their exact locality; but from examinations made with the finger, after they have been opened, I am led to suspect that their usual situation is between the *levator ani* muscle and the pelvis, and that the division of the lower part of this muscle, as well as that of the whole of the *sphincter ani*, is necessary to the cure.

These large pelvic abscesses occur in some instances as the original and only malady. In other cases, as I explained in my last lecture, they are the result of an abscess lower down, or a common fistula. I have met with several cases such as I am about to describe. I have been consulted concerning a fistula near the lower part of the rectum, which I have laid open in the usual manner. But, after some time, I have found that the parts shewed no disposition to heal, or that they healed imperfectly, and that there was a discharge of pus much greater than could be accounted for from the apparent extent of the sore surface. I have thus been led to make a further examination; and at the upper part of the sinus which had been previously laid open, I have discovered a small orifice, through which a long probe might be passed to a great depth. I have laid open the lower part of this upper abscess into the rectum, and could then introduce my finger so as to feel the broad inner surface of the pelvis on one side, and what seemed to be the *levator ani*, on the other. After this second operation the purulent discharge has immediately become much reduced in quantity, and in the course of a short time the patient's cure has been completed.

In those cases in which a *fistula in ano* occurs in connexion with some organic disease of the lungs or liver, I advise you never to undertake the cure of the *fistula*. No good can arise from an operation under these circumstances; but if you perform it, one of two things will happen: either the sinus, although laid open, will never heal, or, otherwise, it will heal as usual, and the visceral disease will make more rapid progress afterwards, and the patient will die sooner than he would have done if he had never fallen into your hands.

ADDITIONAL OBSERVATIONS RESPECTING THE DIVISION OF THE SPHINCTER MUSCLE.

In the course of these lectures on the diseases of the rectum, I have frequently had occasion to speak of the division of the sphincter muscle; but I should leave the subject incomplete if I did not offer some further remarks illustrative of that operation.

I usually divide the sphincter from within outwards, using a probe-pointed bistoury, having the cutting edge slightly convex. I introduce the fore-finger of one

hand into the rectum, which then serves as a guide to the bistoury. This must be introduced a considerable way, so as to be quite above the upper margin of the sphincter, which is then to be cut across, the incision extending fairly into the surrounding adeps. A single stroke of the cutting instrument is not sufficient, and generally as many as two or three are necessary to accomplish this purpose. But in the female subject, whether you divide the sphincter in a case of fistula, or in one of any other disease, I caution you that you should never make your incision exactly in front, towards the vagina. The wound made in this direction does not heal in a proper manner: the muscle, if divided at this point, is never a perfect sphincter afterwards, and the patient labours under an incontinence of fæces, from which she never completely recovers, and which makes her miserable for life. Then, it is not advisable, in either sex, that you should divide the sphincter directly backwards towards the os coccygis. If you do, you will find that the wound does not very readily close, and that it is liable to crack and be reopened afterwards. There is a sufficient anatomical explanation of what I have now mentioned. You will recollect that the *sphincter ani* consists of two parts or layers. The inner layer is circular, embracing the anus like a ring; the external layer on each side is attached posteriorly to the apex of the *os coccygis*, by elastic ligament, and anteriorly to the central point of the perineum. If you cut in the direction backwards towards the os coccygis, you divide, it is true, the inner or circular layer of fibres, but not the outer layer. The knife passes between the two lateral portions of this outer layer, and simply splits or separates them; and the contractile power of this part of the muscle remains, and interferes with the cicatrization of the wound.

MANSLAUGHTER BY BLOWS,

AND FRACTURING THE TIBIA WITH A POKER.

Perth Circuit Court, Thursday, April 14, 1836.

Mary Finlay, of Kirriemuir, was charged with having, in January last, murdered James Finlay, her husband, by striking him with a poker on the legs, dashing the house-door violently against his person, and beating him to the ground, whereby his leg was broken, and he died in consequence about a fortnight afterwards. The panel pleaded Not Guilty; whereupon evidence was produced, of which we will merely give an abridged outline.

Jean Milne, niece of the deceased, and who was servant in the house at the time in question, deponed that on Saturday evening, the 23d of January, several individuals were drinking in the house; that after their departure the deceased attempted to break the dishes in the kitchen with a poker, which the panel wrested from him, and struck him on the shoulder once or twice with it; that the witness having then left the room, returned shortly afterwards, and found the deceased lying on the floor, and the panel striking him with the poker with considerable violence on one of his legs; that after this the panel went to another room, and the witness assisted the deceased to undress, and in taking off his left stocking saw blood on the leg. Deceased refused to go to bed, and went towards the door, which was opened by the panel; and after the deceased got out, heard the cries of murder. The door was shortly afterwards opened, and witness dragged in the deceased, assisted by the panel. It was at this time that witness saw the bone of the leg protruding, and deceased cried out that his leg was broken. The deceased was given to drink, and was drunk on the above evening. Witness had no quarrel with panel previous to leaving her service. Had said, for the purpose of screening the panel, that she herself opened the door to let the deceased out. There was no blood on the sides of the door, or beneath where the leaves met. Heard the deceased request his leg to be released when caught between the leaves of the door as he went out; and when he escaped, the door shut with force. When the door was opened, the deceased was found sitting in front of the door, but there was no mark on him as if he had got a fall. He was almost naked, and the street was wet and dirty.

Other witnesses deponed to the condition in which the panel was on the first part of the evening, and after the accident, in almost similar terms. Several witnesses also swore that the deceased, after the injury, charged the panel with having broken his leg with the poker, and that she expressed much contrition for the sufferings of the deceased.

Alexander Webster, surgeon, was called to Finlay's house between twelve and one o'clock on the Sunday morning. Found him lying on his back on the kitchen floor, the upper part of the shin-bone of the left leg protruding through the flesh. Finlay said it was his wife that had done it with the poker. Witness sent for Mr. Malloch,

and had the bone set. Attended the deceased occasionally until the time of his death, on Monday, the 8th February. On the night of the injury the deceased was intoxicated. His death might be ascribed partly to the injury, and partly to delirium tremens; this made its appearance two days after the injury. Prescribed opiates and a little wine. Finlay was in a low state. Was directed to have the body disinterred, which was done; and the bones of the leg were preserved. They were put up by Dr. Smith, of Forfar, in presence of the witness. Identified the bones produced. Never saw so severe a fracture. A man's leg may be broken by a fall on level ground, but had never known of such a fracture as this from a fall on level ground. Possible to fracture the tibia on level ground, and perhaps the fibula. In general such a comminuted fracture denotes violence — most likely crushing. There were no marks of violence on the limb. Quite possible that the fracture of the tibia might have been occasioned by blows from a poker; but impossible that a man could have walked, however short a distance, with the tibia fractured as this was.

Cross-examined.—Saw no discoloration of the leg, nor of the shoulder. A blow by a hard instrument produces ecchymosis; saw none on the body. A blow, such as to produce even simple fracture, would produce such marks. The fibula would not have carried him two steps after such a fracture of the tibia. Does not think the fracture could have been occasioned by crushing between the leaves of the door, without tumefaction. There was but very slight tumefaction about the wound, and no ecchymosis on any part of the limb; there was no inflammation on the Wednesday afternoon next after the injury; but the delirium tremens continued. Had attended Finlay during two attacks of delirium tremens previous to all this.

Mr. James Syme, professor of clinical surgery in the University of Edinburgh, has had great experience in surgical cases. On the bones being produced, he said it was a remarkable fracture in some respects —in so far as the fracture of the fibula was through the upper end of the bone. That of the tibia also led him to think it must have been done with great violence. Could not be from a simple fall. There are marks which lead him to think the fracture of the tibia had been by a blow: partly from the part of the bone broken, and the appearance of the bone in the neighbourhood, which appears to be dead bone. Thinks the poker might cause the fracture of the tibia. It was possible he might walk a little after fracture of the tibia, supposing the fibula to have remained entire—and though very improbable, yet not impossible, that he might have done so with both bones broken. Had known cases of a person walking after a thigh bone was broken. This is a more extreme case than walking after the tibia was broken, if the fibula be entire. If fractured, and yet not displaced, it would be more possible to do so. The crush at the door might account for the fracture of the remaining part of the bone. The slam of the door might fracture the fibula, or the fall might, after the limb was fixed. Losing his balance, there might be a twist of the limb. There could be no ecchymosis till some hours after. Should have expected ecchymosis near where the fibula was broken, or at any rate within three days thereafter. With an open wound there might be no ecchymosis, if the blood were taken away.

By the Judge.—Difficult to conceive that both bones could have been broken by the poker, or that he could have walked to the door if they had. The tibia might have been fractured and not displaced— and the fracture might have been rendered compound afterwards. Thinks it very probable that there would have been dislocation, if the leg had been squeezed. In absence of dislocation, it was reasonable to suppose there was no squeeze. It was his opinion that death ensued from the fracture. Delirium tremens often comes on after severe fractures, especially those which prove fatal. Excessive drinking will bring on the common delirium tremens, and a person of dissipated habits is more apt to suffer from such an attack after injury. Delirium frequently comes on in a short period after injury. Does not think that this is a recurrence of the same attack he had before. He was no doubt predisposed to the disease, but the fracture was the cause of his death.

Cross examined. — Delirium sometimes comes on before inflammation. It sometimes ensues from withdrawing a stimulus from those who are of a shattered constitution, and often in excitement. The dead part of the bone might be caused by a fall as well as a blow, but it is much more reconcileable to a blow.

By the Judge.—The comminution of the upper part of the bone might arise from a fall, but more likely from the squeeze. If a blow had been given with a poker on the shoulder, he should have expected ecchymosis within three days. To the best of his judgment, a fall on level ground could not have produced such a compound fracture. Had a case occurred in witness's own practice, he should have been inclined to remove the dead obtruding bone: but this was a matter of opinion.

Dr. Alexander Smith, Forfar, was at the disinterment of Finlay, and thinks, from what he has heard to-day, that the fracture of the tibia was more likely to have been produced from a blow. Supposing the fibula entire, it was possible to walk as far as the door. Thinks the blow and the squeezing sufficient to produce the fractures of both bones.

Mr. J. Malloch, surgeon, attended the deceased; inspected the limb very particularly. No external appearances—and from any indications should have supposed no blows given. Should expect ecchymosis from a blow any where. Could ascertain no comminution when he examined the leg. The post-mortem examination agreed with his report during life. The bone was roughly handled after exhumation; so much so as might fracture the fibula and produce comminution. The amputation was performed by the servant of an old military surgeon, who seemed to handle the limb roughly to show his familiarity with such things. His decided opinion was, that the fracture was the effect of a fall, not of a blow. The fracture of the fibula was not observed till the body was disinterred, though the leg was carefully examined, on the morning of the injury, by himself and Mr. Webster.

Mr. Malcom, Perth. Thought the fracture the effect of an external blow. Did not think such a case possible on level ground, without violence. Even the exercise of the leg in walking might break the fibula.

The Crown Counsel here intimated his departure from the charge of murder; when the panel's Counsel called as a witness,

Mr. Lizars, Professor of Surgery in the Royal College of Surgeons, Edinburgh. His opinion is, that the injury was the consequence of a fall. Had it been by a blow, should have expected bruises, or ecchymosis, in the vicinity of the fracture. Had seen fractures on the fibula by a fall, but not quite so near the top as in this case. There was matter in the reports read, which led him to suppose it probable the injuries of the fibula might have been sustained after death. Indeed, it was most reconcileable to that supposition. It was very probable that the fibula was broken at the rough handling after amputation. Thinks it impossible that he could have walked fifteen feet with a broken tibia. It is frequently the case, that when the tibia is broken, the fibula, being a slender bone, is broken in the attempt to rise up. Had the leg been broken by the poker, the appearances could not have been such as described in the medical reports. He should have expected ecchymosis, tumefaction, and ruffling of the skin. These would have been still more apparent on Wednesday. Those appearances would depend, of course, upon the degree of violence. Such violence as to produce the fracture must have caused those. Take away the stimulus from an habitual drunkard, and he instantly has delirium tremens; and that not unfrequently causes death. That, as in apoplexy, may occur on the second, third, or fifth attack. If a person is habitually addicted to delirium tremens, it is very likely to be brought on by such an injury as this, but not necessarily.

Cross-examined.—Has known instances of such a fracture as this by a fall. Violence would, of course, render it more likely. Remembers a case in Edinburgh, where a man falling his own height on level ground, had fractured his leg.

The Lord Justice Clerk then went through the evidence, and told the jury, that as the medical evidence was conflicting as to the cause of death, it was for them to judge whether an injury such as they had heard described as being inflicted on the person of the deceased, was to the danger of life.

The jury found the panel *guilty* of assault with the poker, to the effusion of blood, but recommended her to the leniency of the Court.

Sentenced to imprisonment for twelve months in the jail of Forfar.—Slightly abridged from the *Perthshire Advertiser*, April 21.

MEETING OF THE PROFESSION IN WARWICKSHIRE,

TO OPPOSE THE MEDICAL ARRANGEMENTS UNDER THE NEW POOR LAW.

To the Editor of the Medical Gazette.

Sir,

I send you an account of the proceedings of a meeting held at Warwick, the 14th of April, with a request that you will insert it, together with the Petition which was adopted, in your very widely circulating journal.—I remain,

Your constant subscriber,
J. Wilmshurst,
Chairman.

Warwick, April 20, 1836.

Among the resolutions passed at the meeting were the following:—

1. That this meeting view with surprise and concern certain statements put forth by the Poor Law Commissioners, in the 25th section of their First Annual Report —statements which must have been founded

on few and rare exceptions, not in any degree justifying a general imputation on the character of medical practitioners.

Their feelings on the subject of this imputation might lead them to express themselves more strongly, if they did not feel that they might confidently rely for its refutation on the opinion of the public in all parts of the country, concerning the disinterestedness, humanity, and honour, of the medical profession.

2. That it appears to this meeting that the system of obtaining medical attendance upon the sick poor adopted by the Poor Law Commissioners, is arbitrary and inconsistent on their part, degrading to the profession, and deplorably inefficient as a provision for the sick.

3. That a petition be presented to Parliament, pointing out the inefficiency and injustice of the system of providing medical attendance upon the sick poor, as adopted by His Majesty's Poor Law Commissioners; and that every medical practitioner do acquaint any members of parliament to whom he may be known with the circumstances of the case, and request their support of the Petition, of which the annexed is a copy.

4. That the medical men now assembled belonging to the Provincial Medical Association, request the Council of that Association to insert an invitation in their next annual circular, for all other medical Societies in the three kingdoms to meet them at Manchester in August next, and to engage proper rooms for the discussion of all questions connected with parochial arrangements.

And, 5. That Sir Eardley Wilmot be requested to present the Petition to the House of Commons, and that the different Members of the Borough and County of Warwick be requested to support the same.

We subjoin the Petition:—

To the Honourable the Commons of the United Kingdom, &c.

The Petition of the undersigned practitioners of medicine and surgery in Warwickshire and the adjacent counties,

Sheweth,

That the system of contract by tender, adopted by His Majesty's Assistant Poor Law Commissioners, for providing medical attendance upon the sick poor, is inefficient and unjust.

1st. It is inefficient, Because in the allotted districts the amount of population is generally scattered over too great an extent of country for any individual to render that prompt and immediate assistance which many cases of illness and *all* accidents require.

2d. And it is unjust, Because, whilst it does not afford proper medical relief to the sick poor, it does not offer a remuneration to the medical practitioner proportionate to the laborious duties required of him; but, a remuneration actually inferior to that allowed for attendance upon criminals.

Therefore your petitioners pray that your honourable house will be pleased to refer this subject to the consideration of a Committee.

Signed by the Chairman, and a large number of medical gentlemen of Warwick, and the adjacent counties.

MEETING AT WORCESTER.

THE NEW POOR-LAW AGAIN.

A NUMEROUS meeting of practitioners of medicine and surgery, resident in the city and county of Worcester, was held on the 19th instant, "to take into consideration the propriety of presenting a memorial to government, on the mode in which medical relief is administered to the sick poor under the new Poor-law Act."

The Mayor, C. H. Hebb, Esq., filled the chair on the occasion.

Dr. Streeten opened the proceedings, by calling attention to some results which had arisen out of the new poor-law act, and which had given great dissatisfaction to the profession. The method of contracting for medical relief to the poor was greatly altered by throwing several parishes together into unions. Dr. S. particularly objected to the system of obtaining parochial medical relief by tender, and also of giving a district of perhaps twenty-five miles to the charge of one individual. He concluded by proposing a memorial. It sets out with complaining of erroneous statements made in the first Report of the Poor-Law Commissioners, which was calculated to injure the medical profession, and to operate to the disadvantage of the sick poor. The memorial then proceeds to point out, that the proposal of the Commissioners to obtain medical aid for the poor by means of tenders from medical men, is degrading to the latter, and injurious to the poor; as, under such a plan, little regard can be had to the fitness of the practitioner. Another evil is, that the districts hitherto marked out, are too extensive to allow of the poor being properly attended. After contradicting the allegations of the Commissioners that medical men have made high charges to parishes, and that there have been collusions between them and the parish officers, the memorial proceeds—"It is no doubt well

known to your Lordship, that the best services of all classes of the medical profession have ever been given gratuitously in the cause of charity, which we take leave to say is more than can be claimed by any other class of professional men; and that this circumstance alone should have protected them from such degrading allegations as are to be found in the report referred to." The memorial concludes with the expression of a hope, that a full inquiry into the best mode of affording adequate relief to the sick poor will be instituted.

The memorial was adopted by the meeting.

It was then moved and carried, "That the Mayor be requested to present the memorial to Lord John Russell, and that the Members of both divisions of the county be respectfully solicited to accompany him."

The Mayor said, that if they were of opinion that his being a medical man, and at the same time holding the office of Mayor of this city, would induce the noble Lord to pay attention to their memorial, he should with great pleasure undertake the task. He thought the subject one of great importance to the profession, and to the sick poor; and he begged his medical brethren, either by word of mouth or by letter, to give him any hint or information which might be likely to insure success.

Dr. Hastings read a communication, addressed by Alfred Power, Esq., Assistant Poor-Law Commissioner, to the Guardians of the Poor, dated Cowbridge, 11th February, 1836. In this paper Mr. Power suggests that the union shall be divided into districts, each under the care of a medical officer, and that the contract shall be divided into two branches—the pauper and the independent; the former including those who are paid for from the parish funds, and the latter of those of the labouring class who shall become annual subscribers to a sick club; the rate of payment per head in both cases to be the same. The terms of annual subscription, it is proposed, shall not exceed the following:—For an individual maintaining himself or herself, 3s.; a man and his wife, 4s.; each child in a family (and if one be subscribed for, all must), 6s.; for every person in the same family, above the age of sixteen, 2s. But this contract not to include midwifery cases.

It was then moved and carried, "That the Lord Lieutenant of the County be respectfully requested to present the petition to the House of Lords; and that the Hon. Col. Lygon and G. R. Robinson, Esq., be requested to present that to the Commons."

Moved by Mr. Hill, seconded by Mr. Walsh: "That an Association be now formed, to be entitled the Worcester County and City Medical Association, for the purpose of affording to his Majesty's Government such information relating to this subject as may be required, and that the Mayor (C. H. Hebb, Esq.) be appointed President."

Mr. R. Hill was requested to act as Secretary, and accepted the office.

Thanks were then voted to the Mayor, upon which the meeting adjourned.

ON PURULENT METASTASIS.

By Dr. R. Froriep.

Dr. Froriep is of opinion that the materials going through the capillaries to the blood are in a state of solution, and do not contain globules; for the porosity of the membrane is not sufficient to permit the passage of globules of pus: so that the appearance of such globules must be coexistent with the effusion of matter. Hence it is incorrect to suppose that a direct discharge of globules of pus takes place into the sac of the pleura, the peritoneum, or the cavity of the arachnoid, as is said, in purulent metastasis; and it is equally erroneous to imagine that, when pus ceases to be secreted from the surface of a sore, it has been transported in the current of the circulation, and deposited in some internal organ, where inflammation is going on.

The mechanism of the formation of the so named purulent metastasis is a follows: if, during the presence of external suppuration, by any contingency, inflammation comes to be kindled up in some internal organ or other, in consequence of the preexisting affection it is prevented from displaying the ordinary characteristic train of symptoms; but, attaining imperceptibly its full development, ultimately gains the ascendancy of the previously existing suppurative process, in which the discharge is suspended, while the vicarious inflammation, acting upon an organism already enfeebled by disease, pursues a rapid course towards a purulent termination.

In support of this mode of explanation, Dr. F. refers to what has been frequently observed, under such circumstances, on post-mortem examination; particularly to those cases where no deposition of pus is discoverable,—merely a serous exudation, or simply the phenomena of incipient inflammation without the effused products.

In accordance with this view, it is plain that a tonic and stimulant treatment, for the purpose of compelling the pus to flow internally, as is vulgarly said, can only serve to augment the mischief commencing. The measures pursued must be antiphlogistic, proportioned to the strength and

constitution of the patient. — *From the British and Foreign Medical Review.—Wochenschrift f. d. Heilkunde*, No. 8. *Berlin* 1834.

THE PROPER TEMPERATURE OF SINAPISMS.

The volatile oil, on which the stimulating properties of the powdered seeds of mustard depend, is not disengaged or formed unless water is added to them; but it has been imagined that very hot water was preferable to cold. M. G. Fauré, sen. has proved, by many careful experiments, that this is not the case, but that water, when heated to 190° (F.) and upwards, prevents the disengagement of the volatile principle of mustard: consequently, that sinapisms should be made with cold water, and for foot-baths the powdered mustard should be first mixed with some cold water, to which boiling water should be added, to raise it to the necessary temperature. By one of those coincidences, which are not uncommon, the same facts have been simultaneously discovered by MM. Geiger and Hesse in Germany. The most satisfactory rationale is, that the sudden heat coagulates the vegetable albumen which forms a coating to each molecule, that prevents the water acting upon it. All causes which coagulate albumen produce the same effect, such as alcohol, strong acids, &c. Cold water, on the contrary, dissolves the vegetable albumen.—*From the British and Foreign Medical Review.—Journal de Pharmacie, Septembre* 1835.

FUMIGATIONS IN HOOPING-COUGH.

Dr. Dohm, of Heide, in the duchy of Holstein, has accidentally discovered a remedy for hooping-cough, that promises to be of considerable use in that too often obstinate and dangerous disease. Two of his own children, a boy and a girl, (the former one, and the latter three, years old,) had been suffering from hooping cough for between two and three months; during which time several remedies, including belladonna, had been tried in vain. The paroxysms were very frequent and extremely violent, so that the fæces and urine used sometimes to be expelled involuntarily. An accident of this kind occurred one evening during the absence of the father; and, to remove the ill smell thereby occasioned, the bedroom was fumigated, and that to such an extent that the child was enveloped in the smoke. Contrary to the expectation of the doctor, the child had not another attack that night; the cough became much milder, and the repetition of the same treatment soon cured it. This encouraged him to try it in other cases, and he invariably found the paroxysm greatly relieved by it, if not completely stopped. The fumigation was made with the common *species fumales* of the Pharmacop. Slesvico Holst. (Olibani libr. duas, Benzoes, Styr. Calamitæ, sing. libr. dimid., Flor. Lavendul., Rosar. rub., singul. unc. quatuor.) He [we think, very justly,] considers the benzoin to be the most efficient ingredient. — *British and Foreign Medical Review.—Pfaff's Mittheilungen, 1ste Jahgr.*, 1 *und* 2 *Heft.*

COLLEGE OF SURGEONS.

Mr. Green has resigned his seat in the Council, and Mr. Babington, of St. George's Hospital, was last Thursday (28th) elected in his place. Mr. Owen has been appointed to give an extended course of lectures on Comparative Anatomy in the new building of the College of Surgeons.

We understand that Mr. Green has also retired from his duties as Professor of Surgery in King's College. Of his professional appointments it is said to be his intention only to retain that connected with St. Thomas's Hospital.

PRESENTATION OF PLATE.

(From a Correspondent.)

The Pupils of the Aldersgate School of Medicine have presented an elegant silver vase to their Lecturer on Anatomy and Surgery, bearing the following inscription:—

"Presented to F. C. Skey, Esq. by the pupils of the Aldersgate School of Medicine, session 1836, in testimony of their high respect for his professional abilities, and their esteem for his private character."

The reverse has the arms of Mr. Skey, with the motto, "Praise is the reflection of Virtue."

By Jon. Pereira, Esq., F.L.S.

Lecture XXXII.

ARSENICUM, *continued.*

I proceed now to examine the *influence of arsenious acid on the putrefactive process.*

Until the commencement of the present century, it was supposed that the bodies of those poisoned by arsenious acid were unusually prone to putrefaction. This, however, has been satisfactorily disproved, by the experiments and observations of Klank, Kelch, Hünefeld, and others; and it appears, that when placed in contact with animal textures, it acts as an antiseptic. "I have kept a bit of ox's stomach four years in a solution of arsenic," says Dr. Christison, "and, except slight shrivelling and whitening, I could not observe any change produced in it." This antiseptic property of arsenious acid, which has been, in my opinion, fully and satisfactorily proved, sufficiently accounts for the good state of preservation in which the alimentary canal has been frequently found some months after death, in those poisoned by this acid, where it was not evacuated by vomiting or purging.

But there is another effect said to be produced on the bodies of animals, which is not so easily accounted for: I mean, their conversion into a kind of mummy-like or adipocirous matter. The following is an abstract of the phenomena, as deduced from numerous experiments and observations, several of which you will find recorded in Dr. Christison's work. After death putrefaction commences, and is attended with the usual odour; but, instead of increasing in the customary manner, it seems for a time to be at a stand-still, and then a series of changes commences of a peculiar character: the soft parts become firmer and drier, at the same time retaining their structure; the putrid odour is frequently succeeded by one resembling garlic; the skin becomes brown and parchment-like; the muscular fibres and cellular tissue (especially of the abdominal parietes) are changed into a tallowy cheesy-like mass; the liver, spleen, and heart, become dry, while the bowels, lungs, and brain, form a greasy mass. During these processes, it is said that the quantity of arsenic diminishes, probably by exhalation; a circumstance very probable, when we bear in mind the garlic odour emitted by the body, and which has been observed by several writers. The diminution, however, must be exceedingly small. After some time, the cheesy smell disappears, and the body becomes dry and hard. I would remark, that, in some cases, the alimentary tube has been found little changed, or decomposed, although other parts of the body had been completely mummified.

I ought, however, to remark, that some writers do not ascribe these phenomena to the influence of arsenious acid, but to other causes. Jäger tells us, that in his experiments the putrefaction of the bodies of animals poisoned by arsenic seems neither to be retarded nor hastened, whether they were buried or not; but he admits that parts in contact with an arsenical solution seem preserved from putrefaction. Seemann also states, that the bodies of three dogs underwent the usual kind of putrefaction after death. However, that in many cases arsenic modifies the putrefactive process, can hardly, I think, be doubted by those who carefully examine the evidence adduced in favour of this opinion.

Does this mummifying process depend

on the chemical influence of the arsenic; or ought we to refer it to a change effected by the arsenic on the body during life, causing "a different disposition and affinity among the ultimate elements of organized matter, and so altering the operation of physical laws in it?" The latter hypothesis, though adopted by Dr. Christison, appears to me untenable; for, in the first place, there is no evidence of any peculiar change of this kind during life; secondly, that this does not take place appears probable from the putrefactive process commencing after death as usual; and it would appear that the peculiar influence of the arsenic does not commence, or at least is not evident, until this process has existed for some time, and when a garlic odour is evolved by the body. It is, indeed, true that the quantity of arsenic which has been detected in the body after death, is, as Dr. Christison remarks, "almost inappreciably small;" but it is probable that the quantity is much larger than chemists have yet been able to recognize. But it is not at all unlikely that the arsenious acid may enter into new combinations, while within the dead body, and in this way become diffused, probably, in a gaseous state: the garlic odour which is evolved favours this notion, as well as the statement made by some, that the quantity of arsenic in the body diminishes during the progress of the mummifying process.

In connexion with the morbid appearances produced by arsenic, the following remarks, made by Orfila in the *second* edition of the "*Dictionnaire de Médecine*," article Arsenic, deserve notice. "Under certain circumstances, the mucous membrane of the stomach and intestines is lined with a multitude of brilliant points, composed of fat and albumen: placed on burning coals, these grains decrepitate on drying, and produce a noise which has been improperly denominated *detonation*: they inflame as a fatty body when they contain a notable quantity of fat, and exhale an odour of burned animal matter. These *fatty* and *albuminous* globules may be met with in the bodies of individuals who have not been poisoned, and require attentive examination in order to distinguish them from arsenious acid. The best method of avoiding this error is to digest these granular parts with water, and to apply the tests proper for demonstrating the existence of arsenious acid."

Modus operandi.—I now proceed to notice some theoretical points connected with the action of arsenious acid, such as, whether this poison becomes absorbed—whether its constitutional effects arise from its absorption—and on what parts of the body it appears to exert a specific influence. I shall examine the two first points under one head.

1. I believe that *the remote effects of arsenious acid are consequences of its absorption.*—I am led to this conclusion from the following data:—

(*a.*) *Arsenious acid is poisonous to whatever part of the body it is applied, the nerves and muscular fibres excepted.*—For example, it acts when applied to the common integument, to wounds, to ulcers, to mucous surfaces (as the rectum, vagina, stomach, conjunctiva, and bronchia), to serous membranes (as the pleura and peritoneum), or when injected into the veins.

(*b.*) *The constitutional or remote effects of arsenious acid are of the same kind,* though the part of the body with which the poison may have been placed in contact, varies.

(*c.*) *The quickness with which the symptoms come on, and their violence,* are in proportion to the absorbing powers of the part. The quickest death is caused by throwing a solution of arsenious acid into the veins; and when applied to wounds, it acts more energetically and quickly than when placed on the skin.

(*d.*) *The most soluble are the most active preparations of arsenic.*—A solution of arsenious acid is more active in producing constitutional disorder, than the same quantity of the acid swallowed in a solid form. Arsenite of lime, which is less soluble than the free acid, is somewhat less energetic as a poison.

(*e.*) Lassaigne states he found arsenic in the infiltrated pleura of a horse killed by this poison; and Foderé thought he had detected it in the urine. Further experiments, however, are required to prove these statements.

(*f.*) It has no poisonous action when applied to the nerves, whereas it is decidedly poisonous if applied to parts the nerves of which have been cut.

2. *The parts affected by the remote operation of arsenic* are several; but those more particularly suffering are, *the alimentary tube*, *the heart*, and *the nervous system*: in addition I may mention the *lungs* and the *skin*, which are frequently affected in a peculiar manner.

(*a.*) That the *alimentary tube* is specifically influenced, is shewn by the fact that inflammation, and even ulceration, of the gastric membrane, have been produced, though the poison had been applied to other parts; so that when we find these appearances in cases where arsenious acid has been swallowed, we must be cautious in inferring that they arise from the local or chemical action of the poison. The rectum and the stomach are more frequently affected than any other parts of the alimentary tube.

(*b.*) That the *heart* is also specifically

acted on by arsenious acid is proved by the symptoms during life (the anxiety at the præcordia, the quick, irregular pulse, &c.), by the post-mortem appearances (red spots in the substance of this viscus), and by the diminished susceptibility to the galvanic influence.

(*c.*) The specific affection of the *nervous system* may also be inferred, and even the particular part suspected, by the symptoms. Thus the headache, the giddiness, the delirium or stupor, the insensibility, and the congestion of the cerebral vessels, would lead us to infer the affection of the brain; whereas the feebleness and lassitude, the trembling of the limbs, the wandering pains, the impaired sensibility of the extremities, and, lastly, the paralysis or tetanic symptoms, would seem to point out the spinal marrow as the part affected. Some even go so far as to assert that the lower portion of the spinal marrow (*i. e.* the cauda equina), is the part principally disordered. Part of the difficulty of breathing, and perhaps also of the disorder of the heart's action, may arise from the affection of the medulla spinalis.

(*d.*) The affection of the *lungs* has been inferred from the pain, the cough, and the occasional inflammatory appearances after death.

(*e.*) The eruptions and other altered appearances of the *skin*, and the falling off of the hair and nails (sometimes noticed), have led to the idea of the specific influence of arsenious acid on the cutaneous system,—an opinion which seems further supported by the fact of the remarkable influence it exercises in some cutaneous diseases, especially lepra.

(*f.*) The salivation noticed by Marcus, by Mr. Furley, by Cazenave, and others, seems to show that the *salivary* glands are sometimes specifically influenced.

(*g.*) The swelling of the face, and the irritation and redness of the eyelids, deserve notice in speaking of the specific effects of this poison.

Uses.—So powerful a poison as arsenious acid necessarily requires to be employed with great caution, and that we should watch its effects most carefully and attentively. There are, indeed, some who protest against the use of it altogether, as being in the highest degree dangerous, and sometimes fatal, even when given in small doses. Unfortunately, however, we are often obliged to resort to it, inasmuch as, on several occasions, we have no other remedy of equal efficacy; and it must be admitted, that when employed with proper precautions, it rarely produces unpleasant consequences. This justification of the use of arsenic applies principally to its internal employment, for I conceive we are rarely warranted in using it for local purposes—that is, as an external application, because we, in most cases, derive no advantage from it which we cannot gain from many other less dangerous agents; and in such instances, therefore, by using arsenic we are unnecessarily risking the safety of our patient. Even the internal exhibition of it is not, I conceive, in all cases admissible: thus its specific influence over the digestive organs renders it improper where there exist any lesions of these parts.

(1.) *External use.*—Arsenious acid has long been employed as an external application. I have already expressed my opinion, that its employment in this way is seldom warrantable; and, in support of this assertion, I may quote one case. M. Roux, the celebrated surgeon, at Paris, states that he amputated the breast of a girl 18 years of age, on account of a scirrhus of considerable magnitude. After the cicatrix had been several days completed, ulceration commenced, accompanied with darting pains. To avoid frightening the girl by the use of the actual cautery, he applied an arsenical paste over a surface of about an inch in diameter. Colic, vomiting, and alteration of countenance, came on the next day, and in two days afterwards she died in violent convulsions. "I am convinced," says M. Roux, "that this girl died poisoned by arsenic." I could quote several other cases illustrative of the same fact, but shall content myself with referring to Wibmer's work for an account of them.

The following case, related by Desgranges, shows the danger of applying arsenic externally, even when the skin is sound:—A chamber-maid rubbed her head with an arsenical ointment, to destroy vermin. Though the skin was perfectly sound, the head began to swell in six or seven days after; the ears become twice their natural size, and covered with scabs, as were also several parts of the head; the glands of the jaw and face enlarged; the face was tumefied, and almost erysipelatous. Her pulse was hard, tense, and febrile; the tongue parched, and the skin dry. To these were added excruciating pain, and a sensation of great heat. Vertigo, fainting, cardialgia, occasional vomiting, ardor urinæ, constipation, trembling of the limbs, and delirium, were also present. In a day or two after, the body, and especially the hands and feet, were covered with a considerable eruption of small pimples, with white heads. She finally recovered, but during her convalescence the hair fell off.

A somewhat ludicrous instance of the ill effects caused by the external use of arsenic is related by Dr. Paris. A bold empiric, in the neighbourhood of St.

George's Fields, undertook to remove the deformity of bow-legs in a dandy drawing-master, by *rasping the shin bones,* and applying arsenic to the surface of the wound!—in consequence of which, in addition to extensive local mischief, the unhappy dupe became paralytic.

I am aware that Mr. Blackadder asserts the danger of employing arsenic as a caustic consists in not applying a sufficient quantity! A small portion, says he, becomes absorbed, whereas a large quantity quickly destroys the organization of the part, and stops absorption. This reasoning might be admissible, were arsenic a *chemical* agent, which it is not. I, therefore, still hold the opinion, that the external use of it as a caustic is not warranted. It is but right, however, that I should tell you that it has been employed and recommended by many high authorities, among whom are, Sir Astley Cooper, and the late Baron Dupuytren.

Though employed as a caustic, yet it produces no known chemical action on the part. Hence, therefore, some term it a *dynamical* caustic, in opposition to those acting obviously by chemical agencies, and which they term *chemical* caustics. Applied in various forms, it has long been celebrated for the cure of *cancer*, from being the active ingredient of several empirical compounds which gained some notoriety in this disease. For example, Miss Plunkett's paste consisted of arsenious acid, sulphur, and the leaves of several species of ranunculi, the whole being beaten into a paste, and made into balls. The leaves of the ranunculi were employed to destroy the cuticle, which the arsenic was incapable of doing, and to allow this to act on a living part. There are many other quack preparations which have been used for the same purpose, in some of which, arsenious acid, in others, sulphuret of arsenicum, is the active ingredient; but I shall not pursue the subject further.

Notwithstanding the recommendations which arsenic has received as a remedy for cancer, no surgeon, I believe, now places any reliance on it, it having in, I think I may say, every genuine case, disappointed the hopes entertained of its remedial powers. The same remark, indeed, applies to all other remedies: even the knife will not always, nor even generally, save the patient; for in many instances, if we remove one part affected with cancer, the disease will make its appearance in another. Hence some have concluded that it is a constitutional disease, and, therefore, not relievable by local measures. The uselessness of arsenic in cancer, and the danger attending its employment, have led to its almost total disuse.

Besides cancer, there are several other diseases in which it has been used. Sir Astley Cooper, in his Lectures on Surgery, recommends an arsenical ointment, containing a drachm of arsenious acid to an ounce of lard, as an application to hard *venereal warts.* It produces inflammation and sloughing of them. *Lupus* is another disease for which arsenic has been employed. *Dupuytren's powder* is composed of 99 parts of calomel, and 1 of arsenious acid, and was much employed by the late Baron Dupuytren, rather as a specific than as an escharotic, in this disease. In lupus, arsenic is much employed by Biett in the Hôpital Saint Louis, either in the form of Dupuytren's powder, or as an arsenical paste: the first is preferred in females and irritable subjects. The *poudre arsenicale de Rousselot* is prepared by mixing half a drachm of white arsenic with an ounce of cinnabar, and half an ounce of dragon's blood. It may be made into a paste with saliva or gum-water. Cazenave states that he has seen arsenical applications used by Biett, and he has himself many times employed them in lupus, without ever having met with one case of bad effects. Of course it is very necessary never to apply these agents to large surfaces: thus the arsenical paste should never be applied to a surface larger than the size of a shilling.

(2.) *Internal use.*—The following are the principal diseases in which it has been employed internally, generally in the form of solution.

(*a.*) *Intermittent fevers, and other periodical diseases.*—Of all remedies for agues, none appear to have been so frequently successful as arsenic, for it has cured on many occasions when other means (even cinchona) had failed. It was brought in to use by Dr. Fowler, of Stafford, who, finding the great success attending the employment of *Edwards's "Tasteless Ague Drop,"* was induced to examine it with great attention; and his *mineral solution* is intended to be a substitute for this quack remedy. I do not think it necessary to recapitulate even the names of the numerous writers on the beneficial effects resulting from the use of arsenic in intermittents; but shall content myself with saying that it is a most valuable agent. Some have objected to its employment, on account of the occasional ill consequences arising from it; but if proper precautions be used, these are very rare. It is not necessary to intermit its use during the paroxysm, for I have seen it given with the best effects during the attack. Dr. Macculloch states that $\frac{1}{16}$ of a grain of white arsenic, given three or four times a-day, will sometimes cure ague when the liquor arsenicalis (which contains arsenite

of potash) fails; but I confess I cannot help suspecting some fallacy in the observation. In administering arsenic (whether in the solid or liquid form), you should be aware that it occasions less gastric disorder if given when the stomach is filled with food, or at least if exhibited after a meal. The explanation of this is obvious: the mucous membrane then comes in contact with a much smaller portion of arsenic than it would were the stomach empty. Hence avoid giving this solution in the morning fasting. Sometimes you will find it advisable to combine opium with it, in order to enable it to be retained more readily by the stomach. In employing arsenic internally in this as in other diseases, always be on the watch for the occurrence of any of the symptoms already mentioned under the head of slow poisoning by arsenic,—such as the swelling of the face, the redness of the eyelids, the dryness of the throat, ptyalism or sore gums, or gastric irritation; or even symptoms of cerebro-spinal disorder,—such as cramps of the legs, or headache. Indeed, even if none of these symptoms should come on, it is advisable never to continue its use more than two weeks without intermitting a few days, in order to guard against the occasional ill effects arising from the accumulation of the poison in the system. In some cases arsenic is given in combination with cinchona, or the sulphate of quinia. Ague is not the only intermittent disease in which this mineral has been found beneficial; for in various affections of the nervous system which assume this type, arsenic has been found highly beneficial: for example, periodical headaches, neuralgias of an intermitting form, epilepsy, &c.

(*b.*) *Chronic skin diseases.* — In various chronic affections of the skin, particularly the scaly diseases (lepra and psoriasis), eczema, and impetigo, arsenic is one of our most valuable agents. I can confidently recommend it in lepra, having seen a large number of cases treated by it, most of which were cured, and in all benefit derived from its use. Begin with from six to ten drops of the arsenical solution of the Pharmacopœia, three or four times a day. Frequently the disease is relieved without any other obvious constitutional effect: sometimes a febrile condition of the body is brought on, with a slight feeling of heat in the throat, and thirst; occasionally with an augmentation of appetite: the urine and cutaneous secretion often promoted, the bowels may be constipated or relaxed, and occasionally, as I have already noticed, salivation takes place. If the patient complain of swelling and stiffness about the face, or itching of the eyelids, you ought immediately to suspend the use of the medicine. Ichthyosis and elephantiasis are said to have been benefitted by the use of it.

(*c.*) *Various chronic affections of the nervous system* have been treated by the arsenious acid, and with occasional benefit: for example, epilepsy, chorea, and even tetanus. I have seen arsenic used in a number of epileptic cases, and in none was the disease cured. In some the fits occurred less frequently, but, as the disease is exceedingly irregular, it is difficult to decide whether this was the effect of the medicine. In chorea, I have seen advantage now and then accrue from the use of this agent.

(*d.*) *In bites of venomous snakes and of rabid animals,* arsenious acid has been recommended. In India, the Tanjore pill (the basis of which is arsenious acid) has long been celebrated for the cure of the bite of the Cobra di Capello, and other venomous serpents. In hydrophobia it has also been proposed; but I need hardly say we have no evidence as yet of any good effects resulting from its use.

(*e.*) In *chronic rheumatism* and *gout—syphilis, passive dropsies,* and various other diseases also, this remedy has been employed, but with variable success.

Administration.—Arsenious acid has been given in substance, in doses of from $\frac{1}{16}$ to $\frac{1}{8}$ of a grain, made into pills with crumb of bread; but the practice is objectionable. The most convenient and proper mode of employing it is in solution. In the Pharmacopœia, there is a preparation called *liquor arsenicalis,* and which is a mixture of the arsenite and monocarbonate of potash, coloured by the spirit of lavender. It is prepared by dissolving arsenious acid, and the monocarbonate of potash (called, in the Pharmacopœia, the subcarbonate) in distilled water, and adding the spirit of lavender. Every two fluid drachms of this solution contains one grain of arsenious acid. For different individuals, the dose of this preparation varies, in consequence of a difference in the susceptibilities of different individuals to its influence. Hence, therefore, we ought to commence with small doses (say four or five minims), and gradually increase the quantity; recollecting never to continue its use for a long period, without intermission, on account of the occasional accumulation of the effects in the system. I have known as much as fifteen minims taken three times a day, for a week, without any ill effects.

Smallest fatal dose.—In a medico-legal point of view it is important to determine what is the smallest fatal dose of arsenious acid. It is not easy, however, to give a positive answer to this question. Dr. Christison says, "the smallest actually

fatal dose I have hitherto found recorded is $4\frac{1}{2}$ grains. The subject was a child of 4 years old, and death occurred in six hours. In this instance, however, the poison was taken in solution." The powerful effects sometimes produced by $\frac{1}{8}$, $\frac{1}{4}$, or $\frac{1}{2}$ a grain, lead us to suspect that 1 grain *might* produce death. but, as just mentioned, we have no recorded case to offer in proof. Buchner says, death may occur from the exhibition of from 1 to 5 grains. Hahnemann also says, 1 or 2 grains may prove fatal in a few days. Dr. Christison remarks, that this statement cannot be very wide of the truth.

Of course a *repetition* of much smaller quantities may prove fatal.

However, under certain circumstances, enormous quantities have been swallowed with very trivial effects. Some years ago I opened the body of a man who destroyed himself by taking arsenic, and I was informed by the friends, that, about a fortnight previous to his death, he made an attempt to destroy himself by swallowing a quantity of powdered arsenic, which they found, on inquiry at the druggists of whom it was purchased, to have weighed half an ounce. It was taken immediately after dinner, and the only effect produced was violent vomiting. Here it is evident that the distension of the stomach with food saved the patient's life; for, I presume, when vomiting commenced, the food acted as a kind of sponge, and cleansed out the stomach. This unfortunate individual repeated the attempt, and death was the result.

Antidotes.—On account of the frequency of poisoning by arsenious acid, I must notice the method of treating these accidents. Unfortunately we have no substance properly deserving the name of an antidote, though various agents have been proposed as such. Of course substances which envelop the poison, and in this way prevent the arsenic coming in contact with the stomach, cannot be properly regarded as antidotes. Charcoal, magnesia, the hydrated peroxide of iron, oil, albumen, milk (which becomes coagulated), and probably many other substances which at different times have been vaunted as antidotes, act only in this way.

Sulphuretted hydrogen, and the *sulphurets* (or hydrosulphurets), as the sulphuret of potash, undoubtedly effect a chemical change on the poison, but the resulting sulphuret of arsenicum is as active, or nearly so, as white arsenic; while the antidote itself, if taken in excess, acts as an energetic poison. *Lime-water* forms, with the arsenious acid, the arsenite of lime; which probably is somewhat less active than arsenious acid, on account of its less solubility.

As, therefore, we have no antidote on which we can rely, our first object must be to *expel the poison from the stomach.*—To effect this, we may give, if vomiting have not commenced, emetics of sulphates of zinc and copper, use the stomach-pump, and tickle the throat. If vomiting have occurred, it will be sufficient to exhibit diluents and demulcents, to facilitate the expulsion of the poison, and, in part, to moderate the effects. For this purpose lime water, sugared water, milk, white of egg and water, flour and water, or gruel, may be given.

Having removed the poison from the stomach, our next attempt must be to neutralise or *counteract its effects.* Unfortunately we have no counterpoisons, and, therefore, must treat the case on general principles. When the gastro-enteritis is marked, our principal reliance must be on the usual antiphlogistic measures, particularly blood-letting, both general and local, and blisters to the abdomen. One drawback to the success of this treatment is the great depression of the vascular system frequently present, so that the patient cannot support large evacuations of blood. Opium is a very valuable agent. Indeed Jäger seems to regard it in the light of a counterpoison. However, on this point he has probably taken a too exaggerated view of its efficacy; but it is undeniable that on many occasions it is of great service. If the stomach reject it we may employ it in the form of clysters. In some cases of arsenical poisoning constipation and tenesmus are present, and in such, benefit may be obtained from the use of mild laxatives, particularly castor oil.

The second *electro-negative* metal which I shall notice, is

ANTIMONIUM.

History and synonymes.—Although the sulphuret of antimony was known to the ancients, yet the *regulus*, or metallic antimony, was not known until the fifteenth century, when Basil Valentine, a German monk, published the method of procuring it. It is sometimes termed *stibium*; and is said to have derived its present appellation from αντι, *against*, and μονος, a *monk*; in consequence of its having proved fatal to some monks to whom Basil Valentine had given it with the view of fattening them, as he had observed that it greatly fattened some hogs to whom he administered it.

Native state.—Antimony is found native in the *metallic state* — in the form of *arseniet*, *oxide*, and *sulphide.* The last-mentioned one, commonly called the sulphuret, or sesquisulphuret, is that used for obtaining the antimony of commerce.

It was formerly imported from Hungary and Spain, but at present we are wholly supplied from Singapore, which receives it from Borneo. It is brought over as ballast to the vessels. I am informed that about 600 or 700 tons is the average annual importation.

Preparation.—We may divide the process for making metallic antimony into three stages:—

1. *Fusion.*—This process has for its object the separation of the antimonial sulphuret from its gangue, or matrix. It is effected by melting the native sulphuret in a covered crucible; in the bottom of which are several small holes, through which the fused sulphuret passes into an inferior or receiving crucible. The fused sulphuret is called *crude antimony.*

2. *Roasting.*—The fused sulphuret, or crude antimony, is roasted in a reverberatory furnace: by this process the oxygen of the air converts the sulphur into sulphurous acid gas, which escapes, and the metallic antimony into the protoxide of this metal.

3. *Reduction.* — The roasted sulphuret (now become a mixture of oxide and sulphuret) of antimony is fused with charcoal and carbonate of soda: the charcoal deoxidizes the oxide of antimony, while the soda reduces some sulphuret, forming metallic antimony and sulphuret of sodium; the latter of which, uniting with some undecomposed sulphuret of antimony, forms the double sulphuret of antimony and sodium.

Properties.—It is a metal of a silvery-white colour, having a fibrous or laminated texture. It is crystallizable; the primary form of its crystals being an octahedron. Its specific gravity is 6·436, according to Thomson; its fusing point 810° Fahr.; it is volatile. Its atomic weight is 64, and its symbol St.

Characteristics.—It is easily distinguished from other metals, by dissolving it in nitro-muriatic acid. The solution (which is chloride of antimony) throws down a white precipitate, called the *powder of Algaroth*, on the addition of water; and gives an orange-red precipitate of the sesquisulphuret of antimony with sulphuretted hydrogen, or the hydrosulphuret of ammonia.

Physiological effects and uses. — So long as this metal retains its metallic form it is inactive; but in passing through the bowels it sometimes becomes oxidized, and, in consequence, acts powerfully as an emetic and purgative; so that its operation is uncertain. Pills made of it were at one time exhibited in colic, under the name of the *pilulæ perpetuæ* seu *pilulæ emeticæ externæ*, because it was said they did not lose their virtue by passing through the alimentary canal; and at one time an emetic liquid was procured, by digesting wine in cups made of metallic antimony (*pocula emetica*).

In Basil Valentine's work, entitled the "*Triumphant Chariot of Antimony*," the following passage occurs, which favours the etymology of the word antimony already mentioned:—"If a farmer purpose in himself to keep up and fatten any of his cattle, as, for example, a hog, two or three days before let him give to the swine a convenient dose of crude antimony (*i. e.* sulphuret of antimony), about half a drachm mixed with his food, that by it he may be purged; through which purgation he will not only acquire an appetite to his meat, but the sooner increase and be fattened."

Oxides of Antimony.

Four oxides of antimony are described, namely, the *suboxide*, the *protoxide* (called also the sesquioxide), *antimonious acid* (sometimes termed deutoxide), and the *antimonic acid* (called peroxide.) Of these I shall notice the second and third only, the others not being used in medicine.

Protoxide.—This substance is found native under the name of *white antimony*, or *antimony bloom.* Various methods are in use for preparing it; but the simplest is to add water to the chloride of antimony (called in the shops muriate, or butter of antimony.) A white powder precipitates, which is called the *powder of Algaroth*, consisting of (according to Dumas)

Chloride of antimony	82
Protoxide of ditto	18
	100

If this oxichloruret be washed with a solution of an alkaline carbonate, the chloride is converted into protoxide of antimony; chloride of sodium or potassium will be left in solution, and carbonic acid escapes. The Dublin and Edinburgh Colleges order this oxichloruret to be washed with water merely.

Protoxide of antimony is composed of

1 atom antimony	64
$1\frac{1}{2}$ atoms of oxygen	12
	80

It dissolves in muriatic acid, and the solution of chloride of antimony thus obtained gives an orange red precipitate, on the addition of sulphuretted hydrogen.

This preparation is used in this country merely for the preparation of tartar emetic. It is a powerful emetic, and as such has been employed in medicine; but it is said to be variable in its operation. It has also been administered in agues and epilepsies: the dose of it is from one to five or six grains.

LECTURES

ON

DISEASES OF THE NERVOUS SYSTEM.

By M. Andral.

As published in the *Gazette des Hôpitaux*, with the approval of the learned Professor.

SOFTENING OF THE NERVOUS CENTRES.

This condition, whether it result from inflammation or not, requires to be treated of separately. The nervous substance preserves its form, but is softer than natural; in some cases it is transformed into something like bouillie—it is then soluble in water, which takes it up, and acquires a milky appearance. Sometimes the nervous pulp disappears, and the membranes alone remain, filled with an opaque serosity. Even the membranes sometimes disappear, at the same time that the cerebral substance undergoes a more or less remarkable change in its consistence: it may be infiltrated with serosity, injected with blood, have a mass of this extravasated into it, or certain purulent matter.

All these cases which I have just described, are not, however, attributable to the same causes. If we admit as the agent of the softening a disturbance in the nutrition, evinced by deposition of fluid in the more consistent parts—if we then represent inflammation as producing a similar effect—we shall undoubtedly be correct; but it would be a mistake to say that those were the sole causes of softening, for there are certain others, although we are yet in the dark with respect to them.

Softening has been met with at any period of life—from the earliest to the most advanced; but it would appear to be most common in elderly persons. As to its seat, this may be either in the brain or spinal cord; it may also be either partial or general: most frequently it is the former. Thus we have the hemispheres of the brain, the cerebellum, the mesocephalon, &c., separately affected. The disease may in the first instance attack the internal parts of the brain, without implicating the convolutions; in fact, we sometimes see the most internal layers, those forming the lateral ventricles, and even the cornu ammonis, affected. The septum lucidum and corpus callosum may be simultaneously affected, but the former, and the vault of these pillars, are softened more frequently than the corpus callosum. The spinal cord is not exempt: it may be affected in whole or in part: sometimes the anterior column, sometimes the posterior, is alone affected. The symptoms vary according to the seat and intensity of the disease: it is therefore necessary to study it in the different parts to which we have above alluded.

Softening of the brain.—When the hemispheres of the brain are the seat of softening, various disturbances become manifest. The intellect is usually weakened, even at the onset, and soon becomes almost abolished, or at least continuing feeble and obtuse. Occasionally delirium has been observed: this takes place when there is a complication of meningitis with softening. The affection of the powers of motion are pretty constant, and comes on either suddenly or gradually. Thus the patients experience a progressive weakness of the limbs, going on to actual palsy, or this state may supervene at once, without any premonitory symptoms. When to this paralysis are added convulsions, there is reason to believe that there is hæmorrhage in addition to the softening. These muscular contractions are seen in different parts; sometimes they are confined to one limb, sometimes to all: even the fingers or toes may be exclusively affected. In some cases the affection of the muscular system is general, assuming the aspect of tetanus, epilepsy, catalepsy, &c.

Occasionally the motive powers undergo no disturbance, but such cases constitute rare exceptions to the general rule.

The most common lesion of sensibility consists in headache, the precise seat of which varies; sometimes it corresponds in the most striking manner with the actual seat of the disease, but this is by no means constant; the pain also varies much as to its intensity, permanency, and times of return; occasionally it is periodical. Sometimes it ceases entirely, while the disease goes on; at others, it attends the malady throughout its whole course.

The digestive and circulating systems may remain quite undisturbed. In some the pulse is accelerated. When the breathing once becomes embarrassed, this generally continues to increase, and the patient dies with stertor or asphyxia. One form of the disease (a rare one) is ushered in by a sudden loss of consciousness, with hemiplegia, and it is then extremely difficult to distinguish softening of the brain from apoplectic hæmorrhage. Another form is also characterized by sudden loss of consciousness, but accompanied by muscular contractions, which assist the diagnosis; in a third form, there are convulsions; in a fourth, the intellect is entire, but the muscular movements affected, giving rise either to palsy or contractions. In a fifth form of the disease there is nothing remarkable as regards the intellect, but the motive powers are weakened, and this goes

on progressively increasing. Lastly, softening of the brain may take place without any external symptoms which are appreciable; in such case, (which is very rare) the progress of the disease is slow.

Whatever be the form of the disease, its most constant termination is death, which may take place within a few hours, or be postponed for many months. M. Lallemand has laid it down, that the mode in which softening of the brain admits of the curative process, is by the part becoming indurated.

RAMOLLISSEMENT OF THE SPINAL MARROW.

The history of this affection in many respects resembles that of myelitis. It is either general or partial, which latter state is the more common; and, accordingly, we meet with softening of the anterior or of the posterior columns, of the superior or inferior portions, or of the grey or the white substance, separately; and hence disorders of various kinds.

Disorders of the intellect may be present or not, according as the parts possess more or less of their natural firmness.

Disorders of motivity.— In general the power of moving is compromised; yet there have been cases in which ramollissement existed to a considerable extent without affecting the motive powers. Dr. Janson, of Lyons, has published a case in which the spinal marrow was in a state of bouillie for the most part, yet the patient had no impediment in his powers of moving. M. Velpeau has also cited a case in which the cervical portion of the cord was morbidly softened, yet motivity was nowise impaired. In animals, too, which have the spinal marrow interrupted, or liquid, we do not find the moving powers injured. And do we not know that the fœtus, during uterine life, has free power of motion, although its spinal cord at that period is far from having that consistence which it acquires subsequently? M. Rullier relates a case where there was considerable ramollissement, but a communication was maintained between the upper and lower portions of the cord merely by a slight though firm slip: there was no exact relation between the part of the cord affected and the parts of the body capable of being moved: the patient could walk, but his arms were paralysed and contracted.

These cases, however, must be considered only as exceptions: the general rule is, that the greater the ramollissement, the more the motive power is affected; and the affection will be the more marked if it be the anterior columns that are softened. The effects of the lesions of motivity are very various; sometimes they amount to no more than a simple diminution of the moving power, sometimes to a complete abolition. It is not unusual to see the lower extremities paralyzed, and the upper also, at the same time. Nor are the different muscles of the trunk, the bladder, the rectum, or the respiratory muscles, free from danger.

This paralysis, whatever may be its situation, will come on gradually in some cases, whilst in others it will appear suddenly, and without any warning. Whether there be paralysis present or not, contraction of the limbs may occur, and that amounting in some instances even to convulsions. All these several lesions may in turn take precedence of each other; their order is not invariable.

Disorders of sensibility.—These are marked by exaltation, depression, or abolition; or, indeed, by perversion of the faculty of feeling. As in myelitis, but less frequently, the patient may experience a pain along the spine, which will dart occasionally towards the upper extremities. A sensation of cold, tinglings of the extremities, are in some cases the first symptoms. I have seen a lady, who, for two years, felt every day a coldness, followed by a pricking sensation, and which were succeeded by a sort of convulsive motions. There was no pain or other inconvenience; but at the end of the two years there were contractions and paraplegia, and the patient died.

A very limited ramollissement, having its seat in some point very high up in the spinal cord, may give rise to all the disorders just mentioned. Dr. Ulric, of Berlin, has given a case in which the pyramidal and olivary bodies, as well as the left half of the pons varolii, were softened, and the restiform bodies slightly coloured red. The patient felt the first symptoms of his disorder at 18, and died at 26. The progress of the malady was as follows:—For six years a sluggishness, constantly increasing,—the limbs heavy; here was a diminution of motivity. At the end of six years, the sight failing, diplopia, strabismus; soon after, greater difficulty in walking, the gait vacillating; the feet as if glued to the ground at every step. The patient then suffered a violent cold, then a general numbness, with paraplegia increasing and subsiding for a considerable time. Cramps next came on, affecting the extensor muscles of the geat toes. A year after, tetanic spasms seized the muscles of the back, and the paraplegia was converted into paralysis of both upper and lower extremities. The paralysis ultimately became general; deglutition and respiration were impossible, and the patient died with his intellectual faculties unimpaired.

I have said that myelitis may, by the influence which it exerts over the different

acts of nutrition, simulate to a certain degree the disorders incident to that function. The same is true with respect to ramollissement of the cord: and it may be acute or chronic.

Progress of ramollissement.—In the acute form, so rapid is its progress that death sometimes occurs as if from a thunderstroke; sometimes it takes place after some hours, with coma. In some subjects, a few days elapse before coma sets in, but it is preceded by convulsions, contractions, palsy (more or less general), and asphyxia generally closes the scene. In the chronic form, the disease may susbist for eight or ten days, without any well-marked symptoms.

Prognosis.—Whatever be the form the symptoms assume, it is more than doubtful that they will terminate favourably. There are successful cases recorded, I am aware; but who does not know how easy it is to be deceived as to the real nature of the complaint, in disorders of the nervous system? Death occurs, as in myelitis, sometimes with exhaustion, sometimes through failure of the respiratory powers, and not unusually by becoming complicated with some inflammation more or less severe, and often chronic.

Treatment.—For all the varieties of ramollissement we have but one mode of treatment; which, however, is capable of being varied, according to circumstances. Is it complicated with meningitis, and are there symptoms of reaction? blood-letting must not be neglected. But suppose there are no such symptoms—on the contrary, languor and debility? why then the system must be supported: tonics must be administered—quinia, iron, &c. Against the actual ramollissement itself, art can do nothing.

INDURATION OF THE NERVOUS CENTRES.

This disease, which is rather rare, may be either general or partial. That form of induration which affects all the nervous centres at once, is very uncommon: not so, however, that which presents induration limited to certain points.

Anatomical characters.—Independently of the seat and extent of the affection, the indurated parts of the brain resemble, a good deal, brain which has been macerated in nitric acid. In a somewhat more advanced degree, it takes the consistence of wax, or Gruyere cheese. In some cases, still more marked, the brain is glistening and elastic, like fibro cartilaginous texture, but without being actually transformed into it.

Various other changes of structure may be associated with this: for instance, there may be hyperemia or anemia; and, in this latter case, the grey substance becomes white. The induration sometimes coincides with hypertrophy, or with atrophy of the organ: a phenomenon which is also sometimes observed in the liver. But the disease under consideration may exist without any of these lesions. Sometimes the parts immediately around hæmorrhagic deposits, accidental formations, &c. have been found in a state of induration.

No age is exempt from this change: I have seen it in an infant of twenty months; but advanced life is nevertheless the most subject to induration of the brain. It is chiefly met with in the convolutions; but in whatever degree it may be present, it may influence the other parts of the brain. The white substance may be invaded by it, and a case has been related of partial induration of the cornu ammonis. The same lesion has been met with in the cerebellum and spinal cord; even the meninges have been seen thickened, adherent, and indicating the signs of this disease.

Induration of the cerebral hemispheres occupies these parts either in whole or partially. In the latter case one would expect the symptoms to assume a chronic character; but observation proves that the induration may be very acute under such circumstances, although it is not easy to understand this; and the brain then presents the disease in its first degree. MM. Bouillaud, Godet, &c. have seen examples of this; and the accompanying phenomena which they observed were those of the *ataxic* fever of Pinel.

General induration of the hemispheres in the chronic form is but seldom met with: I know of only three authentic instances of it. In these the symptoms were chiefly manifested in the powers of movement and intellect; in one there was idiocy, and in the two others great dulness; in two there was epilepsy; in the third no epilepsy, but gradual weakening of the limbs, and paralysis, alternated with spasmodic contractions. One died at 22 years of age; another, who was first seized at 41, died at 48.

Acute induration of the hemispheres is not common in the partial form; in the chronic state it gives rise to various disturbances. In some there are spasms; in others paralysis. Epilepsy comes on in a considerable number of cases; and in others the intellect is affected. M. Lallemand relates a case where embarrassment of speech alone was observed as coincident with induration of the lobes of the brain.

MM. Serres and Gall quote some cases of induration of the cerebellum; and the latter asserts that in these the genital organs were affected; but I have met with this disease wherein no symptoms re-

ferrible to the sexual system appeared. The spinal marrow is susceptible of induration, either general or partial, and the symptoms vary according to the extent, seat, intensity, &c. of the morbid change of structure: thus we may have paralysis, sometimes of the upper extremities, sometimes of the lower, and occasionally of both upper and lower together.

Treatment.—Here the insufficiency of our art must be acknowledged.

CHANGES IN THE SECRETION OF THE NERVOUS SYSTEM.

Lesions in the secretions may take place in any portion of this system. I shall first speak of those affecting the brain. Cerebral œdema is characterized by a superabundance of serosity,—the brain is infiltrated with it. A serous effusion into the arachnoid or into the ventricles, a state of hyperemia or of anemia, or of softening of the cerebral substance, may exist with cerebral œdema. This disease, of which some cases have been recorded, has not hitherto been observed except in the hemispheres and white cerebral parts of the brain.

The *causes* of the affection vary. Thus we see some who, having previously been in good health, are suddenly seized with œdema of the brain; at other times it manifests itself towards the close of a chronic disease of any organ, but more especially of the brain. It is not uncommon at the termination of softening, and it may show itself singly, constituting an entire disease. Acute or chronic, such is one of the forms presented by œdema of the brain.

More rare in the acute than chronic forms, in which last it is pretty frequent, the affection of which we speak manifests symptoms which at first seem to indicate apoplexy, and indeed it is very difficult to draw the diagnosis. Thus we have coma, loss of consciousness, general and complete relaxation of the limbs. But the resemblance between the two diseases is still more complete when the lungs are implicated, and the breathing becomes stertorous, which is by no means uncommon. In these cases, death may take place immediately, or not till some days after the attack. It is to this affection that the name "serous apoplexy" was formerly given. There is, however, another kind of serous apoplexy, which consists in effusion of serum in the arachnoid membrane.

Is it possible, in the present state of our knowledge, to distinguish between sanguineous apoplexy and œdema of the brain? It certainly is so, except in those cases where the cerebral hæmorrhage is in its highest degree. It is then impossible to say whether we have to do with a congestion, an apoplexy, or an œdema of the brain.

Cerebral œdema has been seen to follow the sudden disappearance of another form of dropsy. M. Dance has related an instance in which it supervened upon ascites.

In the chronic form, this disease is chiefly met with in old people. The individuals, under such circumstances, experience a gradual diminution of the intellectual faculties; their corporeal sensibility decreases, and the motive powers become progressively lessened. The same changes, it is well known, take place merely from advanced age, but they are then much less marked. On examination after death, the brain has sometimes, but not always, been found infiltrated with serum. Certain forms of dementia, the cause of which had been till then unknown, have been explained by the presence of this change.

Treatment.—Nothing very precise can be said on this head; whether acute or chronic, cerebral œdema ought to be treated on general principles, like other kinds of superabundant secretion. Sometimes bloodletting is indicated, particularly where there is reason to apprehend formidable congestions, hyperemia, &c.; sometimes revulsives are required, and are frequently of service, more particularly when applied to the legs, but for this purpose they must be used frequently and freely. The employment of mercury, either in friction or internally, is sometimes of advantage; and the secretions, particularly that of the skin, must be duly attended to.

Accidental productions developed in the nervous centres.—The induration of the nervous centres may be so altered, that morbid productions become substituted for the nervous substance. These productions are very various: they may be tuberculous, cancerous, calcareous, or consist of cysts, hydatids, &c.

Tubercle is one of the accidental productions which has been most frequently met with in the brain. It may be situated in any portion of the encephalon: thus we may have it in the cerebral hemispheres, particularly in the portion lying above the ventricles; in the peduncles, and in the tuber annulare,—any of the lobes of the cerebellum. It has also been met with in the pituitary gland, and in the medulla oblongata; but I know of no instance of tubercle being found in the white cerebral mass of the brain. Exterior to the cranium it may be observed in any part of the spinal cord, but more frequently in the cervical than in the dorsal or lumbar regions. In this part the grey and white

substance are both susceptible of the tuberculous degeneration.

The anatomical characters of tubercle here differ in nothing from those presented by it elsewhere. The size of the tubercle may vary from that of a millet-seed to a hen's egg, and even more; for an entire hemisphere has been found to have undergone this change. Sometimes there is but one tubercle,—sometimes there are many; and when numerous, they may either be aggregated in one point, or disseminated. Sometimes they are confined to one hemisphere, sometimes they implicate both. The nervous substance around the tubercles is not always of the same character: occasionally it is healthy; in others it presents various changes, which are either chronic, such as softening,—or acute, such as hæmorrhage. When the membranes participate in the diseased condition, they become thickened, adherent, infiltrated with blood or with serum, in a manner analogous to what we see in the pleura after inflammation of this part. A copious serous effusion into the membranes may result from tubercles; there is then an acute hydrocephalus, abundantly common in children, and of which they frequently die.

When the nervous substance of the encephalon is tuberculous, the same kind of degeneration is generally met with in other parts of the animal economy, more particularly in the lungs. This is a fact of which M. Louis and I have assured ourselves: but it is necessary to observe, and indeed it is a kind of law, that in persons under fifteen, and who are affected with tubercles of the nervous centres, the lungs remain entire till then, whilst above that age the tuberculous change is coincident in the brain and respiratory organs.

External injuries and attacks of inflammation may be the occasional causes of tubercles, but can never with justice be looked upon as the primary causes. Tubercles in the brain become developed silently and slowly, without ever being able to say to what their presence ought to be attributed; the causes are the same as those of tubercles in general. All ages are not equally exposed to this disease; it attacks children particularly, after the first year, and is frequently seen from 3 or 4 years of age up to 15. After this it again becomes more rare, but it has been seen at 40, 50, and 60 years.

The symptoms of tubercles in the brain are not always identical. In some cases no deranged function or other change announces their presence. In a child enjoying perfect health, for instance, we may have suddenly some formidable disturbance of the nervous system; while in another it is in the midst of indifferent health that the nervous disturbance first shews itself; then a disease which previously had appeared trifling becomes serious. It may happen that the symptoms indicative of peril are displayed but once, and followed by immediate death. One of the most frequent symptoms consists in headache of greater or less obstinacy, and which sometimes becomes periodical. It is a kind of hemicrania which slowly wears out the patient. The power of locomotion may be implicated, and the affection of this is either continued or intermittent, and the disorders may be convulsions of epileptic character, or paralysis, which last is usually continued, and shews itself in different parts according to the form of the disease. The intellect is but rarely affected.

With respect to the nutritive functions, the most remarkable circumstance is obstinate vomiting.

When the tubercles are in the hemispheres of the brain, they are usually accompanied by headache, paralysis, and intermittent convulsions, When they are in the mesocephalon they have no especial signs. I ought, however, to add, that M. Larcher has observed true chorea under such circumstances. Tubercles in the cerebellum are far from rare; in twenty such cases the following phenomena were observed. In 17, disease in the back of the head was the principal symptom; in I there was vertigo, but without loss of consciousness or convulsions; in 7 there was loss of sight; in 5, disturbance of intellect; in 8, paralysis; in 7, violent convulsions; in 5, progressive weakness; in 10, vomiting; in 1, sexual disease (case published by M. Monteau.) In all, the disease made slow progress, and assumed a chronic form; sometimes with acute attacks interposed. After a certain time either the patient sunk under some other disease, or died of the effects which the tubercles produced, and convulsions, with coma, formed the conclusion.

Tubercles of the spinal cord, like those of the brain, are particularly prone to be developed in infancy. The symptoms are such as either irritation or compression of the cord might produce, and consist of various lesions of sensation and motion, according to the part which is diseased. There are some cases wherein hemiplegia takes place, although the centre of the spinal cord was the seat of the morbid change. After a time respiration and deglutition become embarrassed, and death is the consequence. In one case the symptoms resembled those of hydrophobia: the patient died convulsed, and, on post-mortem examination, tubercles were found in the upper part of the spinal marrow.

As to treatment nothing satisfactory can be said. I have seen derivatives, counter-irritation, purgatives, mercurial frictions, &c. tried, but it must be confessed, all without success.

REPORT OF CASES

TREATED WITH

VARIOUS PREPARATIONS OF IODINE.

Presented to the Harveian Society,

By Wm. Maclure, Esq.
Surgeon, one of the Presidents of the Society.

SECTION I.—LOCAL DISEASES.

Case I.—*Hernia Humoralis.*

Mr. L., betwixt 60 and 70 years of age, had a large tumor in the left compartment of his scrotum. Whilst he was riding, on the 18th September, 1829, his horse, taking fright at some object on the road, suddenly reared, and the tumor, driven with violence against the pommel of his saddle, was crushed by the superincumbent weight of his body. He was taken home, and I was sent for. I found him sick, pale, cold, faint, and complaining of great pain in the tumor. The scrotum exhibited a huge and frightful mass, enormously swollen, and very dark from ecchymosis.

In the first place I ordered cordials for the stomach, and hot fomentations to the part injured. After the first shock of the accident had gone off, and the pulse had become fuller, I ordered leeches to be applied to the scrotum, the warm fomentations to be afterwards resumed, an aperient, and a warm poultice to be applied to the part at bed-time. These and similar means were persevered in for the next few days, until the swelling, pain, and ecchymosis, caused by the accident, had subsided, and the part had resumed the appearance which it previously exhibited. As I had never seen the tumor previous to the late injury, I now examined it, to determine the nature of the original swelling, and whether any thing might be done to reduce it.

I found the left testicle to be enlarged to at least twenty times its normal size; it was hard, and still tender on pressure; there was pain in the loins, and a little fluid was felt in the *tunica vaginalis testis;* but it was evident that fluid formed but a small part of the tumor, and that it consisted principally of interstitial additions to the body of the testicle. Nor did it appear to be of a malignant nature; it seemed to be nothing else than a simple hernia humoralis, of long standing, complicated with a degree of hydrocele. It had commenced about two years before, without any obvious cause; but probably some forgotten blow may have given rise to it.

With regard to treatment, after having tried to discuss the swelling by inunction with the camphorated mercurial ointment, which did no good, but rather annoyed the patient, by giving him a sore mouth, I began (17th October) to cause to be rubbed in, an ointment composed of ℥j. of the hydriodate of potash, and ℥vij. of simple cerate, well rubbed together. I also directed him to take, *ter die*, a draught made up of ten minims of the tincture of iodine, and water. These were continued till the 27th, when the draughts were laid aside, as at that time little good had been done, and the patient seemed willing to abandon all remedies in despair. I, however, did not think that the iodine had had yet a fair trial, and was lucky enough to persuade him to go on with the *local* treatment a little longer, though I failed to induce him to persevere with the means meant to stimulate the *general* absorbent system. It was fortunate he did persist; for in less than a fortnight a sensible diminution in the size and hardness of the part took place. This encouraged him to proceed; the declension in size steadily went on, the natural shape of the organ began to be developed, and without much farther trouble or delay it resumed its natural magnitude, and its proper feeling on pressure.

The fluid which had been thrown out also disappeared, and though I have attended the same gentleman frequently for other complaints during the last six years, he has never once alluded to the state of his testis; from which silence I infer that it remains as it ought to be.

Case II.—*Tumor in the Ham.*

A boy came to me with an indolent tumor, of the size of a pullet's egg, in

his right ham. It was exactly in the situation of a popliteal aneurism, but there was no pulsation in it; and I readily concluded that it was nothing of that sort. Here again I tried the ointment of the hydriodate of potash; and by persevering in the use of it for a few weeks, the tumor went away.

Case III.—*Bronchocele.*

I have seen several instances of this affection removed by the combined use of the tincture of iodine, and of the ointment of the hydriodate of potash. The last case I had was that of a young woman in the household of the Lord Chancellor, in which the thyroid gland had reached a considerable size, but which is now happily reduced to its natural dimensions.

Case IV.—*Serous Tumor.*

Mr. A. fell from his horse, and was bruised on the cheeks, about the eyes, nose, &c., and his back was sprained and discoloured. The right eye was closed, and the whole of that side of his face was black and swollen. He had great pain of back when he attempted to move. Leeches and fomentations were applied to both head and trunk repeatedly. Benefit was derived from these means. The case went on without any thing remarkable occurring for more than a week, the swelling and discoloration of the face going off, and the pain of back on moving getting less and less. Whilst using friction, however, with a stimulating liniment, his groom discovered a tumor on the injured spot of the back, and my attention was then called to it.

Upon the right side of the lumbar vertebræ there was a tumor exterior to the longissimus dorsi muscle, which plainly contained a fluid. There was no pain on pressure, no heat, no throbbing, no redness; yet a fluid was felt to move easily within a kind of cyst, which cyst, however, was not full. I determined to open it, and see the nature of its contents. I accordingly made a puncture at its most depending part. I found the wall of the cyst thicker than I anticipated, and was obliged to make another thrust with my lancet before any fluid came. A thin limpid serum first appeared, which was followed by one of a bloody hue. About two ounces in all were discharged, and then the cyst seemed to be empty. Pressure was applied for some days. When looked at again, the wound had healed, but there was still a little fluid in the cyst. I then ordered the ointment of the hydriodate of potash to be rubbed into the part night and morning, and the pressure in the intervals to be continued.

Under this treatment the fluid was gradually absorbed, and the natural appearance of the back restored. Has a tumor of this sort, arising after an injury, ever been described before?

Case V.—*Enlarged Ovarium.*

The next case which I have to detail, as perhaps illustrative of the effects of iodine on the absorbent system, is one of still greater importance than those I have already described—viz. one of an enlargement of the left ovarium in a young female.

The subject of it had been growing larger about the abdomen for upwards of twelve months, until at last she exhibited the appearance of one in the fifth month of pregnancy. The catamenia, however, were regular, and her moral character was unimpeachable. Upon examination the swelling was seen to be confined principally to the left side of the abdomen; and, upon pressure, it was rather obscurely felt to be a circumscribed tumor, occupying the situation which an enlarged ovarium usually does. In general there was little pain felt on pressure; but the tumor occasionally gave rise, in the progress of its growth, to obstructions of the bowels, attended by severe spasms, distention, pain, sickness, and the like phenomena. It was after the subsidence of one of these attacks that I advised her to try the effects of rubbing the ointment so often mentioned over the tumor, and of using iodine also internally. Dr. Locock's opinion at this period was also solicited, as well as that of Dr. Roe, and both these gentlemen coincided in the advice which I had given her. The iodic treatment, as above, was continued for about a fortnight, with, as the young woman supposed, some benefit; but, I confess, I could not discover any diminution of the tumor.

Returning one evening from a meeting of this Society, I received an urgent message to visit this patient, as she had been taken very ill. I found her in the

greatest agony, complaining of violent pain in the abdomen, apparently of a spasmodic nature, and resembling, though it was more severe, the attacks of pain she had frequently before experienced. I ordered for her antispasmodic and purgative medicines, hot fomentations, and the use of opiate enemata, with a view to mitigate the urgency of the symptoms. The bowels having been emptied, and a powerful anodyne given, I left her for the night, somewhat relieved. When I called next morning I was told she was much better, that the swelling in her side had greatly subsided, and that during the night a large quantity of dark-coloured urine, of a very fœtid odour, had been voided. When I examined the part, I was greatly surprised to find that the tumor had almost entirely disappeared, and that, though there was still some pain on pressure, and some swelling, a great change for the better had certainly taken place. The fluid had unfortunately not been preserved, so that no examination of it could be made.

The patient remained for some time in a very weakly state, and there were sometimes returns of acute pain in the situation of the late tumor, requiring leeches; but, upon the whole, her recovery went on very favourably. As soon as these pains had subsided, and the leech-bites were healed, the ointment was ordered to be reapplied, until all hardness and swelling should disappear. This, I understand, has now taken place, but I have not had an opportunity very lately of ascertaining the fact by an examination.

Instances of as sudden subsidence of ovarian tumors, as happened in my case, have, I believe, been known to take place. According to Dr. Mason Good, "Dr. Baillie knew of one instance in which the disease disappeared spontaneously, after it had existed for nearly thirty years, and the patient remained in good health permanently*." It is not stated by Dr. Good whether, as in the case above detailed, there was any unusual flow of fluid from the bladder, concomitant with the subsidence of the tumor.

Besides this case I have heard of some others, in which the tumor as suddenly, though more inexplicably, disappeared; of one, indeed, where it had been determined on to remove the tumor by an operation, in accordance with Mr. Lizars' proposal; but when the patient was laid upon the table for that purpose, no tumor was to be found, and no one could tell whither it had gone! The result of my case, and the way in which it appeared to go, may probably be thought to account for the phenomenon.

Did the iodine contribute in any degree to the agreeable result? Perhaps not.

* Study of Medicine, vol. v. p. 432.

SECTION II.—CONSTITUTIONAL DISEASES.

Case VI.—*Hepatization of a Lung.*

Mr. J. F., aged 18, had symptoms of fever; his head was more than usually affected; there were severe headache, and considerable delirium. Leeches were applied to the temples; an emetic, a purgative, and saline diaphoretics, were successively and promptly administered. By these means the headache and delirium were relieved. He now complained of pain in the scrobiculus cordis. Leeches were applied here also, with benefit. Pain, accompanied by cough, afterwards came on in the right side of his chest. He was bled from the arm to ℥xij. and as much more was taken from the part affected, by cupping. Calomel, antimonials, with saline draughts, were constantly given. The pain of side was by these means removed, but cough, dyspnœa, with inability to lie upon the right side, and a dull sound upon percussion over that side, remained, shewing that a solidification of the right lung had taken place.

An eminent physician was associated with me in the treatment of this case. A blister was applied to the side affected, and the part was kept discharging by the use of the ung. sabinæ. Calomel with digitalis was given; but, in addition to these, Dr. C. consented that we should make trial of the tincture of iodine, given with other things in the shape of a draught, instead of the salines hitherto administered. Under this treatment the right side soon again became resonant, and the patient's power to lie upon it was regained. His cough also, and dyspnœa, went away, and his pulse fell to 72; his appetite returned, and, in short, he appeared to be quite convalescent; but, unfortunately, just a day or two before his intended removal to the country for the restoration of his

strength, he went out for a drive one rather cold day, in an open carriage. This produced great, though not fatal, mischief. All the symptoms of consumption of the most rapid kind, except the *permanently quick pulse*, set in, and produced the utmost alarm for his safety during many weeks. Violent cough, with a copious expectoration, great shortness of breathing, night sweats, and much emaciation, afflicted the patient, and alarmed his friends. The pulse, however, was seldom more than 84 in bed, and never more than 100 out of it; so that, upon the principle which I advocated when detailing J. Jones's case*, I never abandoned the hope of Mr. F.'s recovery.

The result justified my prognosis. After a great deal of treatment, which it were irrelevant here to detail, he recovered perfectly, and is now a remarkably stout young man, upwards of three years after the attack.

John Jones is also alive and well, and at present fills the useful though humble situation of a waiter at the University Club, Pall-Mall East. This interesting fact I think it of some importance to record, now five years after his recovery from consumption, as we all know how much scepticism as to the possibility of such an event was expressed at the time†.

Our associate, Mr. Barker, has had a similar case, equally unpromising in its appearance, in which a fatal prognosis was delivered by the physician in attendance. The pulse, however, was not *permanently rapid*; and, founding upon this circumstance alone, Mr. Barker ventured to differ in opinion from his friend. By judicious treatment the young gentleman recovered, and is now perfectly well.

Case VII.—*Marasmus.*

The Hon. Miss ——, aged 9 years, in the spring of 1835 began, from being a healthy lively girl, to fall off. She became dull; she lost flesh; she was pale; her tongue was red about the edges, loaded in the centre; she had but little appetite, and her bowels were confined, attended with some inflation. To combat these symptoms I at first gave her mild laxatives, composed of the hydr. cum creta, and the pulv. rhei. The motions were at first dark and offensive. After these had become more natural I commenced giving her four grains of the iodide of iron daily, in the form of two draughts. Each of these had two grains of the iodide, seven drachms of camphor mixture, and one of simple syrup,—the formula originally recommended in this Society by Dr. A. T. Thomson. The laxative powder, as above, was continued every second night, to keep the liver and bowels active. Under this plan, in the course of two months she was quite well, her mother, Lady ——, at the conclusion of the treatment, having been pleased to remark, that I had "wrought a miracle upon her;" an observation which, if I were at liberty to name the noble lady who made it, would be esteemed a valuable testimony to the merits of the iodide of iron.

Case VIII.—*Chlorosis.*

I have seen the best effects arise from the use of the iodide of iron in cases of chlorosis. In one remarkable instance, where the symptoms were manifested in an aggravated form, consisting of great debility, dulness of spirits, a waxy paleness of the countenance, great lethargy, quickness of pulse, loss of appetite, palpitations, shortness of breathing, confined bowels, with paleness, thinness, and deficiency of the menstrual flux, I succeeded in restoring a very good state of health to the young lady, by means of a three months' course of this substance. As the liver in such cases is generally sluggish, and the bowels much inclined to be costive, I gave, along with two grains of the iodide three times a day, almost every night a pill, composed of the compound extract of colocynth, and a minute quantity of the pil. hydr. Carriage or other exercise in the open air, a nourishing diet, and a regulated allowance of wine, were also enjoined.

I may here remark, that combined with iron only have I found the iodine to act the part of a tonic; at the same time I must also state, that I have not seen it, under any form, produce that emaciation which the early experimenters with iodine attributed to it.

Case IX.—*Impetigo.*

Master F., about six years ago, when he was only a year old, became affected, after shewing some febrile symptoms,

* Vide Med. Gaz. vol. xiii. p. 113.
† Ibid. vol. xiii. pp. 209, 290.

with a psydraceous eruption upon his chin, attended with great itching and the discharge of an acrid fluid. The spot was at first small; but it gradually enlarged until it covered the whole chin, and surrounded the mouth.

When I first saw him, about four years ago, the eruption showed all the characteristics of *impetigo figurata*. The pustules were small and numerous; they arose upon an inflamed base; they were attended by the most distressing itching, and the discharge was thin, and so acrid, that it produced a similar eruption upon any point which it came in contact with. Thus, the child's bosom became largely affected by the matter from his chin. In the hams there were two very large patches, and latterly the disease on the face extended upwards, nearly as far as the zygomatic arch on either side. The hands, especially the surfaces betwixt the thumbs and forefingers, were covered with it. Upon the whole, the child exhibited a very unpleasant appearance to others; and as for himself, both night and day, for several years, he was kept, by the extreme itching, in a most deplorable condition. He was dull, irritable, anxious; his mind, from the constant annoyance of the disease, and its long continuance, seemed to be less developed than it ought to have been at his age; and the growth even of his body seemed to be arrested. The "vehementius rodit" of Celsus* was painfully experienced in this unhappy case; for at night especially the itching was so great, and the desire to scratch it so irrepressible, and withal so hurtful in its indulgence, that his parents were obliged to gird his hands and arms in a kind of strait-waistcoat, to prevent him from scratching, and to give him anodynes, to lull, if possible, the tingling. In this state the child continued for upwards of three years, "all seasons and their change" seeming to pass over him without other effect upon his disease than to increase it. The usual routine of lotions, ointments, purgatives, &c. &c. was of course strenuously gone through; every thing was frequently given up in despair, and as often resumed, with some modification, when the symptoms were at any time more than usually distressing, but all to no purpose. Fowler's solution had a fair trial; at first apparently with benefit,—at last with none. It was then attempted to change the action of the parts by rubbing a pencil of lunar caustic upon them, but with no success. Dr. Green's sulphur baths, so powerful in many forms of cutaneous disease, were employed for a great length of time, with only temporary advantage. At length the redoubted Morison's pills were called in to our aid; but quackery in this instance, not soon, but after a long trial, was obliged to confess itself as powerless as science had been. Just at this juncture, when every thing was about being given up as useless,—when the disease was raging at its worst, and had resisted all our known resources,—when the child was tormented night and day with the intolerable itching of his face, chest, and hams, tearing them whenever he could get at them, till he made them raw and bloody,—when his temper was in the highest degree irritable, his intellect clouded, his growth stunted, his education neglected, and his parents actually wishing him dead, if such were the will of Providence, rather than see him continue in his then condition;—it was just at this gloomy juncture I was lucky enough to observe a short paper in the MEDICAL GAZETTE*, written by a gentleman signing himself "C." detailing the practice of Dr. Wilson, of the Middlesex Hospital, in various forms of cutaneous disease. In that paper are four cases of obstinate skin diseases described, all of which were cured by the use of an ointment formed of pure iodine ℈ss. and hydriodate of potash ʒss. rubbed together, and afterwards combined with ℥i. of lard. From Dr. Wilson's success I was induced to try this ointment in Master F.'s case; but the strength above mentioned was found to be too great, the smarting it produced having been intolerable. Upon this I diminished the active ingredients one half by doubling the quantity of lard, and, though this still smarted, it was not wholly unbearable. The parts were ordered to be smeared morning and evening with the brown ointment thus made; purgatives were given, and an issue was formed in the neck by means of a blister, and dressing the sore with the unguent. Sabinæ.

In a short time the good effects of this practice were manifest; the itching

* A. Corn. Celsi Med. Lib. v.

* Vol. xiii p. 360.

diminished, the discharge lessened, and the eruption ceased to extend itself. It was upon the 9th December, 1833, that the iodine was first employed, and before the beginning of February, 1834, the disease was cured; though I continued using the ointment for some time after all appearance of disease had ceased, fearing it might recur. Upon the 3d March, my notes state, that "the skin of the face has resumed its natural softness, smoothness, colour, and soundness, whilst that of the hams, breast, and hands, is in the same comfortable condition. The intellect of the boy, too, seems to have made a sudden spring forwards, as if eased of a heavy burthen; for now, instead of being the peevish, irritable, anxious, tormented and tormenting being, he was before, he has become a fine, lively, and clever fellow, with all the buoyancy and playfulness natural to his age."

Before concluding this account of the case, I may state that the subject of it has ever since remained quite well. Sometimes during easterly winds, a slight tendency to the disease may shew itself, but it soon is checked by a fresh application of the ointment.

Case X.—*Venereal Eruption (?).*

A gentleman who had had no primary symptoms for twelve years, and who in the meantime had married and was the father of a healthy family, became, in the spring of 1834, affected with an extensive eruption upon his shoulders, arms, chest, &c. which itched excessively; but which, in all other respects, resembled the eruption of secondary syphilis so closely, that I had but little hesitation in prescribing for him a combined course of mercury and of sarsaparilla. This was continued for some time, but at length I was obliged to devise something to allay the itching, which was so great, especially at night, as frequently to deprive my patient of sleep. The ointment which I had employed with such success in the case of *impetigo* was naturally suggested to my mind,—and I tried it in the present one. I also added to the sarsaparilla the tincture of iodine, and withdrew the mercury, except in the shape of an occasional calomel purgative. My success was complete. The disease gradually disappeared, and the patient has remained perfectly well ever since.

I may remark in this place, with regard to the question which has been lately agitated, whether the preparations of iodine produce ptyalism, that my experience is rather against the proposition that they do so. In none of the cases which I have detailed did I see any ptyalism produced which I could fairly ascribe to the iodine. This much at any rate is certain, that the production of ptyalism by its means in those cases which are suited to its use, does not, according to my experience, seem to be necessary for their cure.

I have no experience of iodine checking ulceration; but Mr. Key's papers on this subject are, I think, very valuable.

REMARKS

ON

SEAMEN AND THEIR HOSPITAL*.

By Arthur Mower, M.D.

Fellow of the Royal College of Physicians, and Visiting Physician of the Seamen's Hospital.

Some notice of our national establishment for "the relief of sick and diseased seamen," if not so purely medical as a detail of cases and the results of treatment, yet appears sufficiently so, to be not entirely out of place when offered to the College of Physicians. It will be allowed, that not one of the large London hospitals presents itself more imposingly to notice than the Dreadnought, once a first-rate ship, with 104 guns, but now reposing peaceably on the Thames as "the Seamen's Hospital." Large enough for dignity, and old enough to be venerable, her name has gathered sufficient reputation to appear with some lustre on her head and stern, as well as in the naval history of Great Britain. A ship, like a residence on shore, may surely derive an interest from a great man having made it for some time his home. During nearly twelve months, and till within a few days of the battle off Trafalgar, the Dreadnought bore the flag of Admiral, afterwards Lord, Collingwood; and on board this vessel were written some of those admirable letters, which render so attractive his published "Life and Correspondence."

The Dreadnought was less early in the action off Trafalgar than others of the British squadron, because she sailed

* Read at the evening meeting of the College of Physicians, April 25, 1836.

less quickly; but when there, she did her duty, and was of especial service in saving lives after the battle, on those days when many of the prize vessels, disabled and dismantled, were driven on shore by storms. Even then, she offered a refuge to distressed sailors, of whatever nation.

The glory of her active days has been succeeded by a highly honourable destiny. She has not been sent to sleep in ordinary, nor degraded into hulks, with some of her contemporaries; but, stationed amidst the continual passing to-and-fro of vessels of all nations, she is ever ready to receive, from any part of them, sailors who require medical or surgical assistance. Like a *sœur de charité*, she is entirely devoted to the service of the sick.

The routine of medical practice in other hospitals can be little varied, except by peculiarities in the phenomena of disease. The patients, with a few exceptions, are of our own nation; and from a class of life daily near us for observation: their personal adventures and feelings, therefore, except as illustrating their maladies, are generally considered too obscure and uninteresting for the trouble of inquiry. We attend to their complaints rather than to themselves, and study pathology more attentively than human nature. In the Seamen's Hospital, the individual himself necessarily excites curiosity, as well as his disease. The monotony of symptoms is there continually relieved by novel traits of character, or the mention of strange adventures, which gives additional interest to the accompanying detail of aches and pains; and these aches and pains, if deserving only common names, and requiring only common remedies, arise, in many cases, from by no means common causes. They are not referred to the uninteresting medium of cold and wet, damp beds, or drizzling showers, which make a land's-man shiver, and send him coughing and rheumatic to an hospital, but to the drenching waves of high and heavy seas; to night-watchings amidst surrounding ice bergs; to exhausting toil during long-continued gales; to the extremes of hardship and of suffering, after a disastrous, and all-but-fatal, shipwreck. Even for his maladies on shore, a sailor frequently provides a cause that has in it something of the energy of the winds and waves that usually excite him. He does not disorder his nerves, or derange his stomach moderately, by quiet sotting, or occasional intoxication, but resolutely keeps himself drunk for weeks together; and after the most perfect devotion to liquor till his money is expended, he comes with horrors, and in a wild delirium, to the Seamen's Hospital. The wind is said to be tempered to the lamb; and by somewhat of an inverse mode of accommodation, the stomach of a sailor seems to be tempered to the strong and fiery liquors it is unmercifully made to endure after a long voyage; and nothing is more remarkable than this power of endurance —except, perhaps, the ease with which such stomachs may be recovered from the consequences of a long debauch. Men, who have been continually drunk for several successive weeks, and during that time have eaten nothing, recover in a remarkably short time from their delirium tremens, by the use of strong opiates, and antispasmodic medicines. They are as if rescued from a most bewildering sea, and drawn, to their great content, into entirely smooth water.

In other hospitals we see how disease is modified by individual temperament; in the Dreadnought, we observe, besides, how it is modified by national constitution. In one bed lies a stout Englishman, from whom 30 or 40 ounces of blood are at once taken away to reduce an inflammation, which is finally to be cured by successive and copious bleedings. In a bed next to him is a negro, as finely formed, and apparently as athletic, as the Englishman, labouring under an inflammation quite as violent, yet by similar venesections, he would be destroyed. The negro is physically and morally less fitted for endurance than other men; his bodily strength is more quickly lowered by active treatment; and his moral nature sinks into hopeless depression at the anticipation of death. The nurses declare that the negroes "die of sulks." When they despair of recovery, it is true that they will take neither nourishment nor medicine; they will speak to no one; and appear to notice nothing. They are literally dead to the world for some days before their dissolution, and their actual death is but the quiet termination of a long and complete fit of abstraction.

A recovery from such a state has been noticed only in one instance. A negro boy, whose complaints were not very serious, suddenly became sulky, and would neither speak nor eat, nor take medicine. He was once observed, indeed, to eat a little bread in the night, as if by stealth, but he became more and more emaciated, and was going, as it were, sideways and silently towards death, after the negro fashion, when the nurse happily thought of offering him some rice. When he could be roused to a glimpse of what was before him, his eyes brightened, and opened more widely; he raised himself, and then saw clearly the luxury which was offered him; he snatched the trencher from the nurse, sprang with it out of bed, and after an imperfect gallopade round the ward, he devoured his rice in ecstacy; and with rice, *ad libitum*, for his diet, he soon got well.

The American blacks do not go out of life so sulkily as the negroes. They are a noble race of men. Their features are more prepossessing, their capacities are more developed, and they have greater passive courage. Speaking perfectly the language, they have much of the intelligence of the Americans, and a mildness and subduedness of manner, which is much more attractive than the democratic bluntness of the true Yankee sailor.

The South Sea islanders occasionally become doggedly ill-natured at the approach of death; but, in general, from their appearance and character, they are a very interesting class of patients. Unhappily, they are too exotic in constitution to bear well the trials of our changeable climate. From the cold, the fogs, and the gin of London, their organs of respiration soon become diseased, and few of them can bear the active treatment necessary for their cure.

It may here be remarked, by the way, that for pulmonary and other complaints to which sailors are most liable, a ship can never be a good hospital. Disorders of the chest, frequently aggravated by the low and damp situation of the vessel, and the necessarily confined air between decks, have at all times a less chance of cure; rheumatisms are more tedious, and, when apparently cured, relapses are more common; chronic dysenteries are more obstinate, and erysipelas more frequent, than in the large and lofty wards of a hospital on shore.

If part of the large Greenwich Hospital could be granted for the purposes, and instead of the Dreadnought, as some of our influential Governors wish and think it might, the ends of the Seamen's Hospital would, beyond a doubt, be more fully answered.

Some of the South Sea islanders are tattooed very beautifully. The skin of one of them, strikingly figured, has been given, by my friend Dr. Roupell, to the museum of this College.

The Welch sailors do not become sulky like the negroes, but they are almost as easily depressed; and they timidly magnify unimportant ailments. They are so distrustful of their convalescence as to leave the ship, apparently not quite sure whether they have any cause to be grateful. Not so the Irish: their loquacious gaiety, even during severe sickness, contrasts with the decorous resignation of the Scotch, and the grave indifference of the English. The Scotch and English, when cured, cheerfully express their thanks; the Irishman not only offers thanks in a double portion, but invokes for you a long life and many blessings. There would be no better practice than amongst a few families of poor Irish, if good wishes and blessings could be converted into ready money.

Sailors, it is well known, have manners peculiar to their order, and a phraseology which is formed by their occupation. In sickness, the sailor characteristics are less apparent; they resume their prominence during convalescence, and are perhaps more remarkable in British seamen than in those of other nations. A French, a German, or a Spanish sailor, is not very different (in speech, at least) from landsmen of the same countries. He tells his tale in simple unfigurative language, as if his early associations with shore remained longer, and were more powerful, than those afterwards formed at sea. The British tars seem more confirmed in nautical phrases; their recollections of land are not so vivid or so attractive, and their language has more constant reference to their ship and to the waters, where they feel themselves so much at home.

What strange histories might we collect in the Dreadnought—what amusing autobiographies might be written there, if the patients could generally write, as well as speak, intelligibly!

A few of them *have* furnished us with written memorials of themselves. A native of St. Helena, who attended constantly on Bonaparte during the whole of his residence in the island, wrote for us an amusing account—and, we believe, a very faithful one—of his experience whilst in the ex-emperor's service. In it we have the world's hero described by his valet; we have Napoleon, the Alpha and Omega of his dynasty, annoyed, like humbler men, with trifles; enraged at the Governor, and scheming fruitlessly to escape; playing the gallant to the young girls in St. Helena; liberal and considerate towards individuals, yet without one generous thought or wish for the general happiness of his race; enduring sickness with fortitude, and dying calmly, if not resignedly—like a soldier, if not like a Christian: refusing the priest whom Marshal Bertrand proposed should see him, "he died, and made no sign."

We had lately in the hospital a native from the English island of New Providence, around whose bed parties of convalescents were frequently collected, to hear the strange and amusing stories he invented and told for their amusement. A tale which he composed and left, fills ten sheets of letter-paper, and is closely and very well written. If, in this production of his fancy, there are some transgressions against good taste, and many grammatical errors, the characters are described very clearly, and are well sustained throughout; and he has certainly succeeded in what Sir Joshua Reynolds asserts to be the great end of art—"to strike the imagination."

We have the autobiography of a sailor of Hindoo descent, who could speak seven languages: it is well written, and very interesting. His life, from boyhood, had been a thirty years of wandering, with more than the usual allowance of adventure and vicissitude. To change his religion from Mahometanism to Christianity, was a prelude to the changeful course of his succeeding years. He was shipwrecked thrice, and once was all but destroyed by assassination. He had been in every latitude, and had visited almost every country on the globe; ran away from ships when not pleased with his pay or treatment; narrowly escaped hanging as a pirate; went on slave voyages to Africa, and gives testimony to the horrors of the middle passage; worked in the back settlements, and floated down the rapids and rivers of America on large rafts of timber; led, with the Indians, the wild life of a savage; and he is gone again to wander, as poor as when he began the world, and still obliged to labour for his daily bread. Such is the fate of most sailors. During their lives, of excitement, it is true, but of severe toil and hardship, they can allow themselves no repose till they are unable to be any longer active; and then, with no provision for the close of life, they are forced to end their days in poverty or dependence.

A large hospital is about to be established for Merchant Seamen; but there will still be a public duty towards sailors left undischarged, so long as Savings Banks are not opened for their exclusive benefit, and their money, by such means, saved to them from the crimps, harlots, and gin-shops, which absorb it so rapidly whilst they are on shore. Mr. Walker recommends Savings-Banks for seamen, very eloquently and convincingly, in his work, "The Original:"—"It is quite melancholy," he writes, "to see how many instances there are of noble and generous fellows falling a prey to the most worthless, for want of a little protection. They have no friends to put them in the right way, whilst they are beset on every side by the most voracious and profligate of both sexes, whose interest it is to decoy them into habits of the most senseless improvidence."

If nothing has been done to assist seamen to an independence against a time of sickness, or the close of life, neither has much been done to assist the better development of their faculties, or give them a higher tone of moral feeling. In our plans for the march of intellect, and for the education of the lower classes, sailors have been forgotten. We are amused with the oddities on the surface of their character, and are unmindful, or unaware, of the improveable nature which lies beneath. Why might there not be a Sailor's, as well as a Mechanic's Institute; where popular instruction should be given on the many subjects connected with a seaman's occupation, and where he might lay in stores of useful knowledge for pleasure and benefit, whether at sea or on shore? A sailor frequently remains many weeks in port; either, when paid off, he waits for another ship, or whilst

the one to which he belongs clears out her cargo. During these weeks he has necessarily much leisure, and were he comfortably lodged, and his money at rest in a Savings' Bank, he might find instruction and profitable amusement at his institute, and from a lending library that might be attached to it. He would, consequently, be less exposed to drunkenness and disease, and the knowledge gained would make him neither less useful nor less happy: assuredly he would not feel less attached to the country which had shown so much interest in his comfort and welfare.

LIFE AND DEATH OF THE CHIMPANZEE.

[An interesting account of all that is known of this species, together with a minute detail of the illness of the individual lately in the Zoological Gardens, is given by Mr. Youatt in the last number of the "Veterinarian." We subjoin the paper in a condensed form.]

The Chimpanzee belongs to the order Quadrumana, the genus Simia, and the sub-genus Troglodytes. From the colour of his harsh and scanty hair, he is called Simia Troglodytes Niger, and, improperly, "the black orang." While the orang utan is of Asiatic birth, the chimpanzee is an inhabitant of the intertropical portion of Africa, and there alone has hitherto been found. He is, probably, the Barris, or great wild man of the African woods, of which vague and often incredible accounts have been given by travellers. Of his natural habits little is certainly known, although he was seen more than 300 years before the Christian æra, by Hanno, the Carthaginian, on one of the islands on the western coast of Africa.

In several peculiarities of structure, the chimpanzee approaches much nearer to the human being than does the orang. Mr. Owen, the sub-curator of the Hunterian museum, and a most unwearied and valuable contributor to our knowledge of comparative anatomy, has drawn, in the fourth part of the first volume of the Transactions of the Zoological Society of London, a very interesting comparison between the osteology of the chimpanzee and the orang with each other, and with man. He has proved that the structure of the former approaches much more nearly to that of the human being than does that of the latter; and, in fact, that the chimpanzee occupies the first step next to man in the descending series of beings.

The animal that is the subject of the present memoir was purchased from a party of natives, at Grand Bassan, on the Grain Coast of Guinea. They said that they had shot the mother, who was nursing it in her arms, 120 miles up the country. It was brought to Bristol, and thence transferred to the menagerie of the Zoological Society of London, where it arrived. It was supposed, from the state of its teeth, that it then was about fifteen months old. It was nearly two feet in height. The natives said that the mother was full four feet and a half in height; but it is the opinion of most naturalists, that the wild chimpanzee is not more than four feet high. It soon appeared to have forgotten its mother and its native forests, and so readily attached itself to those who took notice of it and fed it, that it was liberated from its confinement, and suffered to have the whole range of the ship. It would climb up the rigging with an agility which no sailor could equal. It would spring fearlessly, and at a considerable distance, from one rope to another, courted the notice of every one, and, except when too unmercifully teazed, was always in good humour, and ready for play.

When he arrived at the gardens, a Guernsey frock was procured for him, and a little sailor's hat; and as he sat within his cage, gazing composedly around, as he would often do for a considerable time, he looked like an old weather-beaten sailor, enjoying his well-earned repose. The likeness was too strong to be pleasing; and the writer of this memoir acknowledges that it was long before he could get rid of a feeling of dislike, and almost of loathing, when he paid him his usual morning visit.

He soon attached himself to his keeper, and would play with him, and cuddle him, and was never so happy as when he could throw his arms around him, and bury his head in his bosom. Of this position he was never tired.

He was perfectly obedient to his

keeper, and never offered to bite or to resist him. He was also very much attached to the housekeeper. He appeared to have more fondness for her than for the keeper, and this increased when he became ill; he would then cry piteously to be taken into her lap; but he took liberties with her which he never attempted with the keeper,—he would assume all the airs of a sick and petted child, and once bit her very severely in the hand.

He used to have his face and hands washed, and his hair combed, every morning; and, at the command of his keeper, he would very orderly strip himself for this purpose. He would grasp the cuffs of his Guernsey frock, and draw his arms out, one after the other, as quickly as any human being could effect such an operation: or, if the sleeves of some of his vests were a little too tight, he would turn the body over his head, and so draw out his arms. He never, however, could accomplish the dressing of himself again, although he often attempted it.

He used to enjoy being tickled by his attendants. He would lie on his back, and hollow, and chuckle, and laugh, while they pulled him about—yes! it very nearly approximated to, or was almost the identical laugh of the human being.

He had all the boy's and the monkey's delight of mischief. He would tease the puppies of a Barbary bitch that was in the same room; he would plague the mother—give no rest to another dog that was there; but then, in his turn, he would submit, without any attempt at retaliation, and would suffer himself to be teazed, and not a little roughly handled by them.

When he had not them to play with, or when he was ordered, he would climb a rudely constructed tree in his cage, and would leap from bough to bough, or would get into his swing, and shew himself an adept in the art of balancing himself, superior to the wandering professors of it; or he would play with a large ball that usually lay in a corner of his cage. His countenance would then brighten up to a degree that could hardly have been expected from its usual staid and grave expression. "In his most sportive play, however," says the author of an interesting account of him in the Penny Magazine, "there was nothing of the restless quickness so observable in the actions of the monkey—nothing of that chattering and grinning on every surprise; but a superiority of character, and an approximation of its manners, however distant, to those of the young of our own race." It must, however, be added, that the approximation was very distant—if the phrase may be permitted; and that on no occasion could I discover, and I looked anxiously for it, any indications of intelligence superior, or even equal, to some of the domesticated animals. There was a quiet gravity of countenance and demeanour, which seemed in him, as in many a human being, to cover much lack of thought.

His food consisted of fruit, milk, biscuits, and, now and then, a little cooked meat; his favourite food was raw ripe apples, which were always carefully pared for him, and which he would give to his keeper for that purpose. He began afterwards to be very fond of sugared tea, and occasionally he was clamorous for the porter of the keepers. He would take the cup in both his hands, and lift it to his lips, and drink precisely in the same way that the human being would, except that his lips protruded considerable farther.

He exhibited no aversion to any of the quadrupeds that were occasionally brought within his view. It has, however, been said, that "the monkey tribes have an instinctive fear of the larger kinds of snakes, to which they occasionally fall a prey: it was considered worth the trial to ascertain whether, in an animal so young, and which most probably had never seen a formidable snake, this feeling was fairly displayed. Accordingly a large snake was shewn to him, on seeing which the chimpanzee was at once filled with terror, and hid himself in a corner. The lid of the basket into which the snake was put was then closed, and an apple placed upon it; and though the animal desired the fruit, it would not venture near the lurking-place of its dreaded foe, but by actions and gestures, too plain to be misunderstood, expressed its consternation; nothing, in fact, would induce it to approach the basket. This, with the snake, was at length removed, and the apple was placed upon a chair; then, after a most cautious and keen scrutiny, with many doubts and misgivings, the timid creature at length ventured to take the offered prize. From

this experiment it is plain that the snake is dreaded instinctively even by the largest of the simiadæ."

After all, the real character and habits, and *intellect* of the chimpanzee, remain to be ascertained; and it is to be hoped that the opportunity may yet occur, by the captivity of one of a more advanced age, of forming a more correct estimate of him.

This interesting fellow remained with us, apparently in the enjoyment of perfect health, until the 29th of November, when he was observed to have suddenly lost the use of the left leg. He could not put it to the ground, and when he attempted to do so he cried with pain. In the course of a few hours the use of the right leg was gone: he could scarcely move it at all; it was a crawling kind of motion, and as he attempted to move he cried dreadfully. I was in doubt whether it was a case of rheumatism or cramp. I gave him three grains of calomel, and ordered plenty of friction to be used during the afternoon and night. On the following day he was quite well, and so he continued until

February 27th, when I thought he did not appear to be in his usual health. His appetite failed; he was restless; he had a dull yet anxious countenance; and his paw, when he gave it to me, for by this time he and I were sworn friends, was hot. There was no apparent local affection. He was feverish. I ordered that two drachms of the syrup of buckthorn should be given in his tea.

[The fever continued, and the poor animal lost flesh daily. Several professional men joined Mr. Youatt in consultation at different times, and numerous expedients were tried, including purgatives, mercurials, antimony, bleeding (of which Chimpanzee complained bitterly), opiates, liq. potassæ, &c. All these, however, proved unavailing. The account of the poor animal's sufferings is minute and even affecting; but we can only make room for the conclusion.]

March 25th.—Hope has now quite fled. All his evacuations are involuntary, and although he will sip a little milk when it is held to his mouth, the only notice which he takes of his best friends, even of his old nurse, who loved him almost as if he were her child, was to slowly open his sunken eyes, and gaze piteously for a moment on her or his keeper; and then the lid would droop and fall, and a feeble breathing, attended by a faint moan, were the only indications of life.

I saw him about ten o'clock at night. At eleven, he all at once roused himself, and began to scream violently. He was taken out, and wrapped in a blanket, and held on the lap of his keeper, to whom he clung as closely as he could, frequently feebly raising his head and gazing piteously on his face. This continued about an hour, when the screams became less violent, and assumed a resemblance, painful to hear, to the cries of a sick and sinking infant. This continued until two o'clock on the following morning, when they gradually subsided. He then was evidently attempting to free himself from the blanket, which, with the assistance of the keeper, he accomplished; — then with an effort, of which a moment before he seemed to be incapable, he flung his arms around the keeper's neck, and clenched his hands for firmer hold—he threw back his head a little, and brought it before that of the keeper, gazed intensely on his face, with an expression which the man says he shall never forget; and so he continued one or two minutes, when his hold gradually loosened, his arms fell, and he had died without a struggle.

He was examined on the following day. It so happened that I could not be present, but Mr. Martin favoured me with the post-mortem appearances. "The death of the chimpanzee resulted from great visceral disease. The spleen was tuberculated, and united to the adjacent viscera by strong adhesions. The lower portion of the ileum was extensively ulcerated, and in several places the coats of the intestines were completely destroyed, and, had it not been for extensive adhesions of this part, the contents of the bowels must have escaped into the abdominal cavity. The cæcum also participated in the disease. The mesenteric glands were morbidly enlarged, and the liver was also diseased, its colour being of a greyish yellow, exhibiting the minute portal vessels gorged with blood. The lungs were tolerably healthy, but the substance somewhat firmer than in their natural state. They may be said to have been hepatized in a slight degree; they were, however, unobstructed. Dentition had nothing at all to do with the affair."

ACCOUNT OF THE POST-MORTEM APPEARANCES OF THE BODY,

AND ESPECIALLY OF THE GENITAL ORGANS, OF

THE HERMAPHRODITE DURRGE.

By Professor Mayer,
Of Bonn.

[*From the "Wochenschrift für die Gesammte Heilkunde" of Berlin.*]

The individual whose peculiarities form the subject of the present paper, has been known to the medical public for more than thirty years, by the name, formerly, of Carl Durrgè, but lately as Maria Dorothea Duri. He, or she, was born in Berlin, or Potsdam, in 1780, and christened as a girl. For the earliest account of Durrgè, we are indebted to Hufeland, who, in 1801, published some remarks on the then supposed girl; at that time twenty years old, and dressed in female attire. Hufeland, at this time, pronounced the prevailing sexual character of the person to be feminine; which opinion this post-mortem examination has verified. Durrgè was subsequently examined by other physicians and professors of medicine: many different opinions were formed. The most complete of those which were published is to be found in Marten's "*Beschreibung und Abbildung der M. D. Derrier*," Leipzig, 1802. Durrgè was induced, at this time, to dress as a man, and to allow a personal inspection at the different German Universities.

In 1808 I saw him at Landshut, and in 1816 he again travelled through Germany. In 1817 he visited London and Paris, and came back again through Holland to Germany. He had learned the art of wax modelling, and made several excellent models for different museums. In 1820 (in his fortieth year) he came to Bonn, and I held at that time a public lecture and demonstration respecting him. He was soon afterwards appointed wax-modeller and inspector to the Anatomical Museum.

He died suddenly, in the month of March, 1835, of apoplexy, being then 55 years old. In a memorandum book which he carried about him, were written the opinions of many learned men concerning him; among which were the following, by Osiander and Gall:—

"Carl Derrier (neither Derge nor Dœrges) is worthy of inspection, as being a singularly formed male individual, but especially so since so many learned anatomical professors have not known what opinion to form of his sex: some considering him to be an hermaphrodite, others taking him to be a woman, and one, indeed, conjecturing the presence of a distended (*blasige*) womb. But a hollow or bladder-like womb cannot exist without pregnancy or a distension arising from disease; and a vagina-like sac is no proof of the female sex, else would, in many instances, fistulæ in perineo in a man give him therefore an ampulla vaginalis, and a womanly character; and if nature formed in the perineum of a male child, while still in the womb, a fistula in perineo—if this child also had the urethra cleft down the penis, the testicles retained — and if nature did not perfect these, but left them arrested in their development; and if, in his farther growth, he possessed no beard nor hair in the armpits; if there was no semen; if a projecting larynx and manly voice did not develop themselves; nature would, in this case, have as little formed a woman as the gelding a horse makes it a mare. Many say, that, in this instance, nature has produced a being without knowing what she would make; others describe her as a bungler, who *would* have made a man, but has produced instead an imperfect one, or perhaps a maid.

"But a '*mas læsus*,' in spite of what Aristotle may say, is still no '*fœmina*;' and a '*homo physice effeminatus*' is no '*hermaphroditus*,' and can only be taken for a '*homo dubii generis*' by those whose anatomical knowlege has not taught them what is really masculine and what feminine.

"F. B. Osiander.

"Göttingen, May 21, 1817."

Gall's opinion was the following:—

"The so-named Carl Derrier ought, if he be called after his sex, to be named Caroline Derrier. The construction of the head is that of a woman, long from before backward; the forehead low and small. Although he is now thirty-seven years old, yet he has no beard, and his voice is that of an elderly woman. His larynx is small; the arms and knees are bent inwards, as in the female sex; the breasts are larger, in proportion to his size, than would be consistent with the development of a

man. The hips are those of a woman; in short, the construction and proportion of the whole body bespeak the woman. The enlarged clitoris is not placed over a scrotum, so that it cannot be called the penis of a man: it is placed rather between the great labia, as in the female organs.

"In his youth, the menstrual discharge has occasionally appeared. The organ which he possesses does not also, as in the man, arise behind the inner arch of the pubes, and this alone is sufficient to show that he is not to be taken for a hypospadian, as the Parisian faculty have supposed. Whether or not he possesses a womb, cannot be decided until after death. I would farther remark, that the depressions of the occiput are scarcely to be perceived externally, which betrays a deficiency of the development of the cerebellum; and this perfectly harmonizes with his indifference to both sexes, for there are instances of women who have possessed no wombs, but who have still retained their sexual inclinations.

(Signed) "GALL.

"Paris, Sept. 19, 1817."

There was, then, no unanimity in the opinions of physicians, concerning the real sex of Durrgè. He was said to be male by Kopp, Kausch, Mursinna, Soemmering, Rosenmüller, Osiander, Cooper, Lawrence, Green, and the medical faculty at Paris. He was declared to be female by Hufeland, Gall, and Brookes, of London; others again, as Schneider, Lauth, Schmidtmüller, Rilgen, and others, considered him to belong to neither sex. Also the different parts of the body taken individually, were declared by some to resemble most the male, and by others the female sex. The pelvis, however, was generally declared to be in the proportions of a female — viz. by Rittgen, Willbrand, Blume, Münz, &c.

In my public demonstration, already mentioned, I pronounced my opinion to be, that the two sexes were mingled in this individual. From that time to his death (more than fifteen years), I have had him continually under my observation. He always carried himself as a man, probably in part out of vanity, and shewed inclination to the other sex, but without any decided sexual impulse which would make his preponderating sex more certain. His character was evidently a mixture of manly and womanish attributes. For his small growth he possessed unusual courage, muscular strength, and technical dexterity; (his wax modellings were naturally and correctly executed.) His voice, although it grew stronger and deeper with age, was but shrill and weak; his beard grew sparingly, and all his hair fell off, excepting a few long ones on the back part of the head; his head and countenance were those of an old woman, and with these corresponded the want of teeth, the short neck, the breast, so abundantly supplied with fat, and the position of the arms and feet.

In his twentieth year there was a discharge of blood from his genital organs, repeated three times. Since then there had been no trace of it, but he has frequently had discharge of blood from the nose; he was also slightly troubled with hæmorrhoids; this, however, was in a great measure the consequence of his habits, as he was much addicted to drinking coffee and wine. He was never known to have had nocturnal emissions, or any other seminal discharge. In his twenty-first year he lost his hair through gout in the head, and he was subsequently subject to repeated arthritic attacks, so that gouty secretions were found in many parts of his skeleton. His body was fully developed in his thirteenth year, and since then he has not grown any taller.

In his thirty-eighth year a common change occurred in his body; he became fat, and his voice grew stronger and deeper. From his fortieth year I have known him to be healthy, active, and expert. At this time he was attacked with a nervous fever, at the time of his attendance at the anatomical rooms; this he got through very well. In the last three years his memory, which had been hitherto very good, failed him; he altered much, and entirely relinquished his wax embossing. He died, as has been already stated, suddenly of apoplexy, having been remarked by me to have had, for some days previously, a particularly heavy and fixed aspect.

Description of the Exterior of the Body.

The length of the body was five feet; the length of the upper extremity, from the condyle of the humerus to the point of the middle finger, 2 feet $6\frac{1}{4}$ inches;

that of the lower extremity, from the trochanter major to the heel, 2 feet 10¾ inches. The head is formed like a woman's, small, the forehead narrow and low, and the posterior part arched. The hair is exceedingly scanty, and is only present on the occipital region; beard very slight; the neck is short, and the larynx does not project. The width of the shoulders is 1 foot 2 inches; the thorax is short and narrow; the remainder of the trunk longer; the breasts are moderately projecting; but the nipples, on the contrary, are somewhat retracted. The pelvis is not wide; the arch of the pubes not very diverging; the arms and legs shew a womanlike curve.

Description of the Organs in the Interior of the Body.

The tongue is short, broad, and rounded; the papillæ capitatæ much developed; the os hyoides firmly ossified, but small. The thyroid cartilage weakly developed, is small; but from above to below its cartilage is firm. The thyroid gland is small, but normal; its superior and inferior horns, however, are very strongly marked, as also the corpusculum santorinianum. The ligamenta crico-thyroidea, as well as the cricoid cartilage, are proportionally strongly developed. The epiglottis is thick and strong; the cavitas laryngis is not very wide, but the ligamenta vocalia are in comparison thick and strong. The trachea is rather narrow, and its cartilages are somewhat weaker than in man. The lungs are moderately small, each being divided by a slightly marked fissure into two lobes; the left lung was closely adherent to the parietes of the chest, as also to the diaphragm and pericardium of its side; the right lung appeared quite healthy; there were only a few arthritical tubercles in it, the size of peas; the left, however, contained many more, especially in the inner side of the superior part.

The heart is large, wide, and rounded; its muscular fibre is well developed, and offers nothing irregular; the distribution of the principal vessels at the arch of the aorta is normal; the general form of the heart is that of a woman. The stomach is rather long; its muscular fibre weak. The spleen was adherent to the parietes of the abdomen; it is unusually small, its length being 2 inches 10 lines, its breadth 1″ 8‴. The liver is tolerably large. The gall-bladder contained fifty small blackish concretions, of the size of currants. The remainder of the alimentary canal offered nothing irregular. The cæcum was large, and processus vermiformis wide. The mamma itself is but slightly developed, whilst over and around it there is a great quantity of reddish yellow granulated fat, without shewing clearly the presence of any *glandular* acini. The nipple is very slightly projecting; it shews many openings, which are, however, nothing more than sebaceous follicles, situated in the areola. The kidneys are narrow, and rather long,—on the whole, small; the renal capsules are normal.

The encephalon, and especially the cerebrum, shows, independently of its small size, decidedly the form and structure peculiar to the female. The whole brain is well rounded and arched; the lobes are not very prominent; the convolutions are very numerous, but small; the crura cerebri short and slight; the pons varolii small, as also the medulla oblongata. The cerebral nerves, particularly the fifth, are smaller than in man. The cerebellum is somewhat weakly developed and compressed; its right hemisphere is evidently weaker than the left: this obtains in all its lobes and their subdivisions, but is more especially evident in the lobulus biventer, the tonsils, and the flocci; besides this, the lamellæ of the cerebellum are numerous.

In the cerebrum also the right hemisphere appears to be more slightly developed than the left, which is made especially evident upon the base of the three lobes by a considerable depression. The corpus callosum is proportionally short; the thalami, corpora quadrigemina, pineal gland, and corpora candicantia, small.

The skull, taken together, is of small size; its bones are thin, but firm; the sutures perfectly visible.

The vertebral column is regularly formed, but the individual vertebræ, especially of the neck and back, are weak; the ribs are weak and flat. On the left side, the third, fourth, and fifth ribs appear to have been broken in two places; the seventh in one. They are, however, for the most part, reunited. This probably occurred from a fall in his earlier life. He did not complain of pain in the part. It was on this side

that the left lung was adherent to the costal pleura. The sternum, especially the manubrium, is proportionally strong. The whole thorax is narrow, particularly the upper half, whilst the lower is more capacious. The bones of the upper extremity are strong, although they preserve the proportion of a woman's; this is very evident in the scapula and clavicle; the latter is short, roundish, thin, and much bent. The fore-arm forms a very evident angle outwards with the upper arm; the hand is as small as a woman's. The lumbar vertebræ are not large in proportion to other parts, whilst, on the contrary, the sacrum is strong and broad; its promontory does not project much.

The pelvis consists of strong thick bones; it is in its whole narrow, and shows a remarkable manly form. Its transverse diameter, between the cristæ ilii, at the widest part, is nine inches; the distance between the anterior superior spinous processes, 7 in. 3 lines. The proportions of the brim of the pelvis are these: — Antero posteriorly, 3″ 4‴; transversely, 4″ 5‴; obliquely, from the sacro-iliac synchondrosis to the junction of pubes and ilium, 4″; transverse diameter of the lower aperture, 3″ 3‴; antero-posterior, 2″ 6‴. The symphysis pubis moderately long and small; the foramina obturatoria are rather long; the proportion of the angle formed by the pubes is that of a man, giving about 65°; the lateral portions of the ilium are directed upwards, and the acetabula lie more forwards; the tubera ischiadica are directed backwards and inwards; the whole pelvis is somewhat irregular and oblique, so that the right side of the inferior paries is narrower and smaller than the left, whilst at the same time the promontory is bent more towards the left side; the bones of the lower extremity likewise show no particular degree of firmness; the collum femoris is extremely short, the trochanters are but slightly marked, and the knees are bent inwards.

Description of the Genital Organs in particular.

The mons veneris is slightly arched; the hair on the pubes is small in quantity, and does not extend as high as the navel,—it is also scanty and weak on the labia, the perineum, and around the arms; the length of the penis to the corona glandis is about 2 inches; the glans itself measures 9 lines in length; the greater part of the penis is retracted beneath the skin of the mons veneris; the corpora cavernosa are moderately developed, showing a perpendicular diameter of 8 lines, and taken together, their transverse diameter is 4″,—they are separated by a septum; the corpus spongiosum urethræ is of course wanting; the prepuce covers only one half of the glans,—at its extremity, and on the inferior surface, is a small depression, fossa navicularis, from which point arises the semi-canal, which represents the urethra slit up. This half canal is formed by two folds of skin, which separate from one another wider posteriorly, and so in some measure resemble nymphæ. This channel leads to a round opening, of the size of a large quill. The great labia form, by means of their wrinkled skin, the projecting under-lip of this opening; the lateral and superior portions are covered with smooth mucous membrane. It is on each side of this upper portion that the lengthened folds are situated which represent the urethra. On the under side are seen traces of the carunculæ myrtiformes. This opening is situated in a vestibule of eight lines in length, which is extended upwards as the urethra, and backwards in a wide canal, which represents the vagina. The septum, which in this part divides the vagina from the urethra, is crescentic, and lies horizontally. The urethra, beginning thus at the root of the penis, is immediately surrounded by the prostate gland; which body is decidedly firm, but not very thick. Here are found some large openings, which are in part mucous follicles; in part, however, the emissory ducts of the prostate gland. The neck of the bladder, as also the bladder itself, is regularly formed; the membranes of the latter are firm, and the muscular fibre is well developed.

The canal which represents the vagina consists of a mucous membrane, having beneath it numerous delicate muscular fibres; in it was some greenish mucus. It is surrounded at its commencement by a vascular reticulated tissue, from which it can be easily separated; and this tissue, which consists for the most part of distended varicose veins, extends upwards between the vagina and urinary bladder. Here it becomes gradually

lost, and in this part the principal trunks of the veins leave it; and here also a considerable artery advances to distribute itself in its texture. The openings of the ureters offer nothing unusual.

The length of the vagina is 2″ 8‴, its width is anteriorly ten, and posteriorly six lines. The inner surface is rather corrugated at its commencement, but afterwards it is smooth, and is provided with very fine papillæ, and has, also, some star-like reticulated spots resembling cicatrices. The vagina terminates in a still more constricted and closed position, which consists merely of a spongy tissue, and is from four to six lines in length; behind this isthmus, which is, indeed, the closed orifice of the uterus, lies this organ itself, which, maintaining the same oblique direction taken by the vagina, is situated between the bladder and rectum, but it inclines itself throughout more to the left side; so that the fundus lies quite on the left side of the urinary bladder. The length of the uterus is 2″ 3‴; it is, however, but small in proportion to its length. Its cervix and fundus may be distinguished. It is at first furnished only with a thin skin; farther, however, its inner surface shews some slight folds and spots of a yellowish brown colour. It contained some gelatinous mucus. The cavity of the uterus was still smaller than the *constricted* portion of the vagina, and would scarcely admit a large quill, still the fundus was wider; its transverse diameter was six lines. On its inner surface were distinctly-marked furrows; it was very vascular, and contained some vesicles resembling hydatids, and here and there some yellow spots. Both the Fallopian tubes open regularly into the fundus uteri; the left is the shorter, its length is 3″ 4‴; the right is an inch longer. Their canal is indeed narrow, but quite perfect, even to the ostium abdominale; which, however, on one side was closed by several distinct hydatids. The ala vespertilionis was evident, and beneath it were some tolerably strong muscular fibres, which passed from the fundus uteri and upon the side of the urinary bladder as a bundle, and, directing their course through the abdominal ring, became lost in the fat covering the pubes. Upon the right side, close to the abdominal end of the Fallopian tube, there is a small flat oval body, to which a string of vessels and muscular fibre is attached

This body is entirely surrounded by peritoneum; it is about as large as a small almond, and its texture consists evidently of a weak yellow fibrous tissue, exactly corresponding with the testicle, and, indeed, the seminal canals can be drawn out of it. The string before alluded to consists of a spermatic artery and vein. On the left side, however, is observed, behind and without the corresponding ostium abdominale of the Fallopian tube, a small round flat body. It was covered by peritoneum, and shewed, after its removal, a granular parenchyma, consisting of separate globules, so that its texture seems to assimilate to the ovarium rather than to the testicle.

We have, therefore, found an union of male and female characteristics in the development of this individual, but certainly less decided than I have found in another Hermaphrodite—the so-named Maria Göttlich,—which individual possesses the most revolting combination of the attributes of the two sexes,—inheriting, on the part of Hermes, imbecility instead of wisdom, and from Aphrodite, ugliness instead of beauty.

The principal male characteristics in Durrgé, are the withered testicle, the penis, and the prostate gland; on the other hand, the uterus, vagina, Fallopian tubes, and the ovarium-like body found on the left side, all bespeak the woman. I consider also the deficiency of one hemisphere of the cerebellum to be a circumstance worthy of remark; this, indeed, had been already conjectured by Gall, in consequence of his indifference to both sexes. The cerebrum, and especially the cerebellum, were imperfectly developed on the right side, and upon the opposite side was found, in the abdomen, only that ambiguous body more like an ovarium; whilst, on the contrary, on the right side was a testicle, although contracted.

PHYSIOLOGY OF THE HEART'S MOTIONS AND SOUNDS.

To the Editor of the Medical Gazette.

Sir,

The letter of Mr. Blyth, in your valuable journal of April 9th, relative to my observations on the "Heart's Action

and Sounds," induced me to reperuse what I had then written, in order to ascertain how far I had rendered myself fairly liable to the accusation of being both verbose and unintelligible.

I confess, with the exception of some verbal inaccuracies *, I have not been able to discover just reasons for Mr. Blyth's unqualified condemnation, and cannot help partly attributing Mr. B.'s conclusions to his not having followed my suggestion, of carefully studying what I advanced, with an opened healthy heart before him. If he will also carefully perform the experiment I have described at the close of my paper, he will perhaps discover that some portion at least of my remarks merited a more indulgent reception. The sentence especially selected as a specimen of my obscurity, and which I am "defied to explain," is only faulty from the word "auricular" being accidentally omitted before "systole,"—an omission the context, I should conceive, would have supplied to any attentive reader; and though a critic might carp at the phrase "*muscularly tightened,*" yet, when associated with what was stated relative to the anatomical connexions of the valves, it is at least free from any obscurity.

One object I had in view was to insist on the fact, that the mitral and bicuspid valves, particularly the latter, are more or less tightened by the contraction of the muscular fibres to which their tendons are attached; and since muscular contraction necessarily precedes the fluid pressure in the ventricle, the valves could not be regarded as passive up to the moment of their being acted upon by the blood; and from the fact of their being in a state of tension *before* they experienced the full pressure of the ventricular contents, that they were physically incapacitated for the production of sound in the manner usually ascribed to them. I attempted to strengthen this view of the subject by referring to M. Bouillaud's description of the form and divisions of the ventricular cavities, mentioning my own belief of its accuracy, founded on frequent personal examination; and if Mr. B. "cannot see the truth of this arbitrary argument," as he styles it, I conclude that he speaks rather from former reminiscences, than from any recent inspection of a fresh and healthy heart.

I also wished to fix the attention of observers upon the relations which the blood invariably maintains with the cardiac cavities, insisting on the fact of their never being, at any one moment, an *empty space* in either the ventricles, auricles, or vascular system; and from these and other considerations which I need not repeat, endeavoured to direct the attention of observers to the different acoustic phenomena produced by the circulation of fluid through shut and constantly filled cavities, from what results from the passage of the same fluid over the same surface, where these physical conditions do not exist. I illustrated my meaning by an experiment, the value of which I leave for the determination of those who will take the trouble to repeat it.

Mr. B. has taken great pains to prove the absurdity of the term "*gradual*" being applied to a phenomenon so rapid as the descent of the blood from the auricle into the ventricle. The word was not intended to represent duration so much as to indicate the difference between the falling of fluid into an empty and previously dilated ventricle, and its entrance into the same cavity, during the act of dilatation, and maintaining an accurate approximation with the expanding parietes. The latter I conceive to be a more gradual process than the former.

My opinion respecting the absence of conflicting currents and molecular collisions, in any degree sufficient for the production of sound, was founded, not upon the *slowness* with which the blood entered the ventricle, but upon the close and perfect contact it preserved with its walls, whose movements it accompanies rather than follows. Though there may be "no difficulty in allowing that there must be conflicting currents and collisions of the fluids," yet when we are investigating them as efficient causes of sound, it is necessary to go farther, and prove, not only that they exist (which no one denies), but their sufficiency to produce the effects assigned to them. In reference to this last point, the following experiment may be deemed applicable. Let the en-

* Page 1016, 2d column, line 15, *for* "diastole," *read* "systole;" page 1017, 1st column, line 29, introduce "auricular" before "systole;" same page, 2d column, line 53, ditto ditto; page 1019, 2d column, line 41, *for* "returning," *read* "retiring."

tire body be immersed in water at sufficient depth to prevent any agitation on the surface being heard, and the arm moved backwards and forwards, so as strongly to agitate the fluid: it will be found that the ear, though immersed in the same fluid, is very slightly conscious of the disturbance; but if similar motions are effected sufficiently near the surface, so as to involve a certain quantity of air and water, the presence of conflicting currents is at once palpable. Let this result be compared with what takes place in the India-rubber bottle, which, from the roughness of its internal surface, is certainly less favourably adapted for the noiseless ingress or egress of fluid, and let the reader draw his own conclusions, as to the efficacy of fluid currents and molecular collisions, as causes of either of the sounds of the heart.

As I really do not understand how Mr. B.'s allusions to the sounds produced by water on the bottom of a boat applies to the subject we are discussing, he will excuse my not replying to what he appears to think a very forcible objection. I am also accused of wisely getting over the difficulty of explaining the particular cause of each sound, by the general terms in which my paper is couched. To this I reply, that it was a matter of indifference to which sound I referred, since my remarks were directed to the analysis of certain alleged causes of sound in general, and were intended rather to prove what was *not* the source of sound than what was. Secondly, there is ample evidence for an attentive reader, that it was the first sound I was really considering; and lastly, my belief regarding the cause of the second sound coinciding with the now commonly received opinion that it depends on the reaction of the blood on the sigmoid valves, I did not think it necessary to make any special allusion to the subject.

The principal part of Mr. B.'s letter is occupied in the attempt to disprove the existence of any sound resulting from muscular contraction; which, at the close of my paper, I casually mentioned as the probable cause of the first sound of the heart. My conclusion is founded on the experiments and reasonings of others, and since it was only accidentally expressed in the paper in question, I must refer Mr. B. to the last edition of Dr. Williams's work on the Diagnosis of Diseases of the Chest, where he will find the subject ably discussed, and, to my mind, satisfactory replies to the objections he has ingeniously advanced.

Mr. B. must certainly be unacquainted with what has already been ascertained on the subject of the heart's action, to think it necessary to refute the opinion of the auricular systole being the cause of the second sound; an idea which I have no where either implied or expressed.

I have thus, sir, as briefly as I could, replied to the letter of Mr. B., and have been induced to do so because I believe that gentleman to be actuated by no other feeling than a love of truth; because his remarks more or less implicate your editorial discrimination; and because I feel they might tend to prevent an impartial examination of considerations which I still believe are not without importance, when endeavouring to determine the true causes of the cardiac sounds.

In conclusion, I would advise your correspondent to leave, for the future, what is unintelligible to its inevitable fate, and not to risk injustice by passing judgment upon opinions which, as he himself acknowledges, he does not understand.—I remain, sir,

Your obedient servant,

CHARLES COWAN.

Bath, April 26, 1836.

REMARKS ON

OPERATIONS FOR ECTROPIUM AND LAGOPHTHALMOS.

By T. WHARTON JONES, Esq.
Of Cork.

(Communicated by Dr. Mackenzie, of Glasgow.)

MY DEAR SIR,

IN your last letter you ask me what I think of Jaeger's operation for ectropium and lagophthalmos, of which there is an account, by Dr. Wm. Brown, in the MEDICAL GAZETTE for February 6, 1836. In reply, I must say I do not think well of it; indeed, so little calculated does it seem to me to succeed, that if it had not been affirmed by Dr. Brown

that Dr. Jaeger had successfully performed the operation, I should have doubted the possibility of its succeeding.

For the operation to do good, the integuments must be very much stretched, and in this state rendered unnaturally adherent to the margin of the orbit, else, on the removal of the bandages and plasters, they would return to their former position. The separation of the integuments from the os frontis, I should fear, would be followed by the formation of abscesses. I do not see the advantage of slitting the eyelid through and through transversely, separating the integuments from the os frontis, through the wound thus made, and afterwards uniting the edges of the *same wound* by suture. The separation of the integuments from the os frontis seems to be the essential part of the operation; and could not this be done as well from above, by making a small cut through the integuments, at the proper distance from the edge of the orbit, and through that opening introducing the straight double-edged scalpel, with which to separate the integuments from the bone from above downwards (in the case of the upper eyelid), thereby avoiding the slitting through of the eyelid altogether? As to the transverse elongation of the lid, this might be remedied by the excision of a wedge-shaped piece.

I have lately put into practice, in bad cases of ectropium and lagophthalmos, a mode of operating, the principle of which, you may remember, I formerly suggested to you, and, in reference to a case of lagophthalmos from a contused wound on the superciliary region, to Dr. Rainy. In the last edition of your Treatise on the Diseases of the Eye (p. 217), my suggestion (which, by the by, is put down as a modification of a plan of Dr. Ammon's, which it is not; for the principle of it is quite different from that of Dr. A.'s operation) is as follows:—"The skin, to the distance of an inch or an inch and a half from the adhesion, is to be firmly stretched, so that the morbid connexion between the lid and the orbit is completely exposed. Two incisions, at such a distance from each other as to include between them the morbid adhesion, are now to be carried from the edge of the orbit, at first perpendicularly, but afterwards inclining towards each other, so that they shall meet at an acute angle, at the distance of about an inch and a half from the edge of the orbit. Beginning at the angle thus formed, the flap is then to be dissected off very cautiously, so as not to cut through the thin and indurated part of the adhering lid. The eyelids are now to be closed, the bleeding stopped, and the flap so placed, that after it has adhered, the previously everted lid shall retain its natural position. The flap is to be fixed in its new situation by stitches, and the angular gap, left by its separation from its former place, is to be closed by the same means. A compress and bandage are then to be applied."

In the cases in which I have operated, the eversion and shortening of the lids had been caused by the contraction of the skin consequent to burns. In performing the operation, I have not ventured to separate the skin from the bone, but have been satisfied with the elongation to the everted and shortened lid, obtained by the stretching of the loose cellular tissue uniting the triangular flap of skin to the adjacent parts. It is to be feared that the complete separation of the flap would be followed by sloughing of it, especially in cases of contraction from burns, in which the texture of the skin is so much injured, and its vitality impaired. In my first operation I made the flap come to a point; the point sloughed: in my second operation I did not make my incisions meet towards the apex of the flap, but left between them a space, about one-sixth of an inch, which was divided by a transverse cut.

The following is a short account of my first case:—

Betty Sullivan, aged 24, has her face much scarred. Both eyes are quite exposed on account of shortening and eversion of the upper eyelids. On the left side, the eversion of the upper eyelid is not so great as on the right. On this side, the ciliary edge of the tarsal cartilage corresponds to the edge of the orbit, and the opposite edge of the cartilage occupies the usual position of the tarsal edge, so that when an attempt is made to close the eye, it is the orbital edge of the tarsal cartilage which is pressed down. There is some degree of shortening and eversion of the left lower eyelid; the eversion becomes very apparent when an attempt to close the eye

is made. Sees very well with the right eye, but with the left, of which there is some opacity of the cornea, does not see well enough to recognise a person. Mentions that at the age of one year and three months she fell into the fire, and had her face severely burned, which is the cause of the state in which she now is. Says that she had an operation performed on the left eye two years ago, and that it was improved by the operation. It is probable that the eversion only had been lessened by the operation, for the shortening of the upper eyelid is still very great.

On the 22d February, 1836, I operated on the left upper eyelid. I made two incisions through the skin, meeting each other at a point. By pressing down the flap thus made, and cutting all opposing bridles of cellular tissue, &c., but without separating the flap from the subjacent parts, I was now enabled to bring down the eyelid nearly into its natural situation by the mere stretching of the subjacent cellular tissue. A piece of the everted conjunctiva was snipped off. Having done this, I brought together, by suture, the edges of the gap left by the drawing down of the flap, and retained the eyelid in its proper place by plaster, compress, and bandage. It was not necessary to diminish the length of the lid transversely. During the healing of the wound, a small piece of the apex of the flap, which had been too much separated from the subjacent parts, sloughed. The parts are now healed; the eversion completely cured; the cicatrice where the part sloughed is pretty broad. When the bandages were first left off, the eyelid was so much elongated, that if the lower lid had not also been shortened, the eye would have been entirely covered. Since leaving off the bandages some shortening has taken place, not from contraction of the skin, which, being no longer stretched on the forehead, is assuming, with the contraction, more the appearance of healthy skin. The left upper eyelid is, notwithstanding, still so much elongated in its perpendicular direction that the eye is very well protected, and, if the lower eyelid were elongated by an operation, the covering to the eye would be complete.

A fortnight ago I operated on the right upper eyelid. I made the incisions in a nearly similar manner. By the stretching of the subjacent cellular tissue, I succeeded in elongating the eyelid so much as to cover the eye entirely, but in consequence of the long-continued displacement of the tarsal cartilage, the ciliary edge remained considerably projecting beyond the surface of the eyeball, whilst the opposite edge continued in apposition with the eyeball. I did not interfere with this state of the parts by attempting any transverse shortening of the lid.

In the operation, I removed a piece of the everted conjunctiva, and with it a bit of tarsal car ilage. From the exposed surface of the cartilage there sprung out a small soft fungus, which I cut off with the scissors. The part was then touched with the lunar caustic pencil.

I remain, my dear sir,
Yours very faithfully,
THOMAS WHARTON JONES.

Cork, 1st April, 1836.

Dr. W. Mackenzie, Glasgow.

ARE MIDWIVES TRUSTWORTHY?

To the Editor of the Medical Gazette.

SIR,

EXPERIENCE has thoroughly convinced me of the necessity of restricting and regulating the practice of midwives. Many governments provide duly instructed and licensed women to attend upon the poor; but with us the midwifery of the humbler classes is left to work its own way, and to add, in no trifling degree, to the number of human calamities. Nobody with the least opportunity of observation will venture to deny that the ignorance of midwives is a very serious evil.

Man-midwifery is advocated by the profession, and sanctioned by the public, upon the ground, that by superior skill and management of women, both during and after labour, much of the actual pain and peril of parturition is spared, and the occurrence of many grave complaints altogether prevented. But since a great proportion of midwifery among the poorer classes falls, as a matter of necessity, into the hands of women, the competency of midwives in general to discharge their duty is of the first importance to the public.

In the city of Norwich, containing a large poor population, the attendance of medical men is small, compared with that of midwives. Two of the older midwives deliver nearly 400 women in the year. The following inscription may be seen on a tombstone in the church-yard of St. Helen:—"Sacred to the memory of Mrs. Phœbe Crew, aged 72, who, during forty years of midwifery-practice in this city, attended 9730 women."

There are only a few midwives in this city who have received instruction*. The greater part have acquired errors of practice from one another; or, commencing as nurses, have boldly entered upon a course of mischievous midwifery: they are very ignorant, very confident, and never apply but in extreme cases; in short, their common practice is barbarous. Besides forcibly dilating the external parts, and making far too frequent and rude examinations, they evince an utter and reckless disregard of the perineum. I have often been shocked at the destruction of this important part in the female economy. I will adduce a few examples, by which I wish to prove that *midwives are not trustworthy*.

In the course of four years my attendance has been required in the following cases:—In foot-presentations, where by hard pulling (without first adjusting the diameters), the head was impacted in the pelvis: in arm-presentation, in which the midwife, not able to ascertain the presenting part, ruptured the membranes at the commencement of labour: in face-presentation, mistaken for breech, by a midwife of great repute, who assured me my attendance was required only to confirm her opinion: in hæmorrhage during labour, where the flooding was suffered to go on to an extent that recovery was at first precarious, and in the end very protracted; and in other cases of hæmorrhage, both with placenta retained and after its removal, in which complete ignorance was shewn of the signs afforded by external examination, and a total neglect of pressure by hand, or support by abdominal belt. Lastly, in the case of a woman subject to flooding during the separation of the after-birth, it was the midwife's constant practice, immediately after labour, to get the patient upon her legs, that the coagula might the more readily come away; or, to use the midwife's words, "to make her a clear woman."

I might mention other instances of malpractice on the part of midwives, of which I have heard, as after-birth torn away in part; navel-string snapped off; the arm broken, or, when presenting, pulled down; sloughing and ulceration of soft parts from protracted delivery, or their laceration from the child being precipitately forced away, &c.; but I ground my remarks upon what I have witnessed myself.

If you will allow this plain statement to appear in the Medical Gazette, the subject may chance to fall into more able hands. The instruction of midwives is an humble, but really a very necessary and important matter; and I shall be glad to see the attention of the public directed to it.

I remain, sir,
Your very obedient servant,
F. Borrett,
M.D., M.R.C.S., Accoucheur to the Norwich Lying-in Charity.

Norwich, April 26, 1836.

* At the establishment of the Norwich Lying-in Charity, in 1832, it was resolved—"that all midwives admitted to act under the Charity be instructed by the accoucheurs;" and country subscribers were requested to select in their own, or adjoining parishes, suitable persons to be instructed in practical midwifery by the accoucheurs of the Charity. Besides the midwives thus instructed, two have received instruction in London.

ANEURISMAL NEEDLE,

INVENTED BY DR. MOTT.

[The Description communicated by Mr. Mayo.]

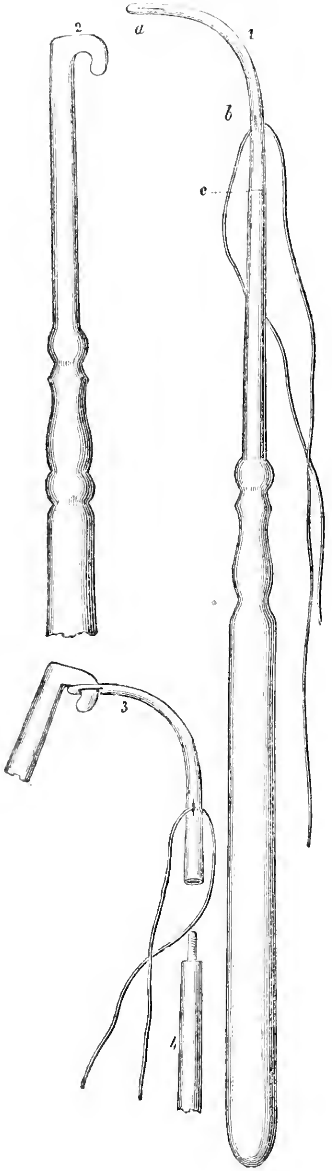
The adjoined figures represent this instrument.

1. The aneurismal needle armed: it has two eyes; that at *b* is intended to receive the ligature; that at *a* is intended to receive the extremity of a blunt hook, after the needle has been passed below the artery.

2. The blunt hook, which is to be introduced into the eye (*a*) of the needle, to fix and steady it, when the latter has been passed below the artery; so as to allow the operator to unscrew the handle of the needle. The place of the screw is at *c*, fig. 1.

3. The needle detached from the handle, and ready to be drawn up with the ligature on the other side of the artery.

4. The male screw, in which the handle of the needle terminates.



The difficulty hitherto experienced has been to make an instrument which would at once be steady and firm in the hand while passing below the artery, and at the same time allow the needle part to be afterwards readily caught on the other side of the vessel, detached, and drawn out of the wound. Dr. Mott's aneurismal needle is perfectly adapted to fulfil all these objects.

George-street, Hanover-square,

ANALYSES AND NOTICES OF BOOKS.

" L'Auteur se tue à allonger ce que le lecteur se tue a abréger."—D'ALEMBERT.

Lectures on Subjects connected with Clinical Medicine By P. M. LATHAM, M.D. Fellow of the Royal College of Physicians, and Physician to St. Bartholomew's Hospital. 1836.

THESE lectures have already appeared in the Medical Gazette, and are now reprinted in one neat moderate-sized volume. We strongly recommend them to our readers; particularly to pupils attending the practice of our hospitals. They will tend greatly to assist the due appreciation of symptoms, and contain numerous original opinions and important practical facts expressed by the author, in a style sometimes quaint, but at all times peculiarly his own. As to the plan and matter of the volume, in truth they are unlike any thing we have in the English language ; and perhaps the simplest method of conveying an adequate notion of them to our readers, is to quote Dr. Latham's own account of them, as contained in the Preface :—

" Considering the time of life at which the majority of those who are intended to practise physic begin their professional education, few can be supposed at once to understand the objects with which it is conversant. I have therefore endeavoured to put in as clear a light as I could, what is the nature of Facts and Opinions, and Theories and Principles, in medicine; and what concern the clinical student has with each; and how important it is for him rightly to distinguish between one and the other.

"With respect to the mode of conducting his inquiries at the bed-side, I have suggested to him how to observe and what to observe; what demands his present attention, and what may wait the season of his more mature experience; what books to read and what to abstain from reading; and the sort of knowledge which is principally auxiliary to clinical medicine.

"But the subject to which I have chiefly desired to direct the student's attention is Semeiology, or the Doctrine of Symptoms; not for the sake of pointing out the symptoms of particular diseases, but of showing what symptoms are in their own nature; what sense, or rather what various senses, they bear; and what is their import and value in enabling us to judge of all diseases which are capable of being known and treated in the living man. For this purpose I have constructed no system, and have adopted only so much of arrangement as was necessary for the convenient discussion of the subject

"The lectures now published, embrace one part only of Semeiology. The inquiry, as far as it has gone, has been occupied with the evidence, which each organ is capable of furnishing, of its own diseases by symptoms directly referable to itself, and involved in the actual state of its sensations and functions and structure. This is the simplest and the easiest part of Semeiology.

"Among such direct symptoms, I have chiefly dwelt upon those by which Auscultation has enabled us to make discovery of diseases of the lungs.

"Auscultation is capable, I have thought, of being greatly simplified for practical purposes. At all events, unless it be so, it can neverbe successfullytaught; the knowledge derived from it must be confined to a few physicians of hospitals, and the profession at large can never expect much benefit from its use.

"Whether I have succeeded in accomplishing what I think so desirable, and have cleared Auscultation of its mystery in any degree, others must judge. But thus much I can safely say, that the intelligent student, by attending to the few characteristic sounds which I have pointed out, and taking pains to understand their import, and guarding himself against over-refinement, is able in a few weeks to discern the leading truths connected with Auscultation, and in a few months to use it and trust it as his safest guide in the diagnosis of pulmonary diseases.

"Such are the objects which these lectures have in view. They do not pretend to teach the clinical student any single thing peremptorily or dogmatically, but only to furnish him with certain aids and assistances by which he may be better able to teach himself."

A Treatise on the Diseases of the Eye and its Appendages. By Richard Middlemore, M R.C.S Surgeon to the Birmingham Eye Infirmary, &c. In 2 vols. pp. 809 and 844. London, 1835.

This is a very elaborate and comprehensive work, containing the results of the author's individual observation and experience, together with an abundant harvest gathered from the labours of his predecessors in the same field. The style is perspicuous, and the matter, whether original or selected, is, for the most part, unexceptionable: blemishes might certainly be found*; but it would be difficult to find a work, extending to nearly seventeen hundred pages of close letter-press, of which the same might not be said; and we have no hesitation in offering it as our humble opinion that the work will be found a very useful manual, by those interested in the pathology and treatment of diseases of the eye.

An Essay on the Laryngismus Stridulus, or Croup-like Inspiration of Infants. To which is appended, Illustrations of the General Principles of the Pathology of Nerves, and of the Functions and Diseases of the Par Vagum, and its principal Branches. By Hugh Ley, M.D. &c. &c. Illustrated with Plates. pp. 480. London, 1836.

Dr. Ley's views on the several subjects treated in the present volume, were fully brought before the readers of this journal, in a series of valuable papers published by that gentleman in the Medical Gazette, in 1835. The papers alluded to have been here brought together, so as to present the observations and experience of the author in a more

* We have received the letter signed "Philalethes," but think his remarks hypercritical.

continuous and elaborate form. The pathology of the disease is further illustrated by several well-executed plates, showing the effects of enlarged bronchial glands in compressing various nerves.

An Introduction to Botany. By John Lindley, Ph. D., F.R.S., L.S., and G.S. 1 vol. 8vo. London, 1835. Second edition, with corrections and numerous additions.

The lengthened notice, and the praise we bestowed on the former edition of this work, render it unnecessary to devote much space to the present. We merely intend to point out the alterations and improvements which have been made in this volume, compared with its precursor. Though it contains only twenty-five pages more than the preceding edition, yet a great deal of room for the introduction of new matter was gained by throwing out the fourth chap. of book iii., the omission of which we recommended when discussing the merits and demerits of the first edition. The room thus afforded is far more instructively occupied by more ample details respecting botanical geography, a subject which Dr. Lindley was the first to introduce into an English elementary work on botany. Also, a portion of the space thus gained, is appropriated to embodying the discoveries and views on the most important points which have been made in the interval since the former edition was published, embracing a period of three years. Thus, much of the most valuable parts of Decandolle's "Physiologie végétale," many of the ingenious investigations of Brown, Brongniart, Mirbel, Mohl, Slack, and Fritzche, have been incorporated into the text of the original. The interesting views of Braun on the spiral arrangement of leaves have been treated of, and elucidated, principally with the aid of the diagrams of Professor Henslow, whose liberality in communicating them, deserves the highest eulogium. The only other English work in which an explanation of this beautiful law of vegetable development is to be found, is Professor Henslow's "Principles of Descriptive and Physiological Botany," which we so lately noticed. Taken altogether, we have no hesitation in pronouncing this Introduction to Botany, by Dr. Lindley, to be the most valuable and perfect in any language we are acquainted with; (and our acquaintance with elementary works on botany in different languages, is not very slight). We, therefore, recommend all those who desire to become acquainted with botany as a science, to procure this volume. Though the quantity of matter has been increased, and the wood-cuts are more numerous, the price is the same as that of the former edition.

MEDICAL GAZETTE.

Saturday, May 7, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

Cicero.

MANAGEMENT OF PAUPER PARISH CHILDREN.

Enough, one would think, enough to make the heart sick, has already been made known concerning the workings of the new Poor-Law: yet, much as has transpired, a great deal more, we fear, remains behind, still to be disclosed to an offended and indignant public. We may say we have hitherto only seen the Poor-Law functionaries in their dealings with adults: adults, however, the impression is, can generally help themselves, or at least seek some redress; but what are pauper infants to do? We can conceive nothing more revolting than the cruel, unfeeling treatment of helpless children — treatment, more especially, having much the appearance of being deliberately planned for a fatal purpose. What is commonly called *infanticide*, though a capital offence according to the laws of most nations, is, in our view of it, far less criminal. Pride, fear, hatred, revenge, or some other headstrong wilful motive, may operate in the one case, where the victim, too, is hardly considered a regular denizen of the "breathing world;" but, in the other, one sole motive can be

assigned—the hypocritical sordid one of economy—a heartless grudge of a little paltry expenditure, and that where the victim has already begun to be a rational being, susceptible of its hopes and fears, and capable, with ordinary attention, of being made a useful member of society.

It is now about six weeks since the newspapers reported a very extraordinary inquest held on a pauper child, at the Workhouse of St. James's, in Poland Street. Some most appalling facts were elicited in evidence: yet we did not think ourselves authorized to comment on the details, as then published, as there was but too evidently considerable party feeling mixed up with the whole proceedings. Since, however, a principal witness has laid the full particulars before the public*, conceiving himself, as it would seem, placed in a predicament which required the whole truth to be known, we have no hesitation in availing ourselves of the documents collected by him in his interesting pamphlet.

The verdict pronounced at the inquest just alluded to, was a special one—setting forth "that the death of the deceased child was caused by mesenteric disease of a severe nature, produced by a scrofulous habit of body;" and the jury added, "that no blame whatever attached to Mr. Aubin, the person at whose establishment the pauper children are put to nurse, &c."

We have no intention whatever of meddling with the facts relating to the particular death which gave rise to this inquiry. Our observations are rather directed towards the system of management adopted with regard to pauper parish infants.

At Norwood, it appears that there is an establishment kept by a Mr. Aubin, at which some hundreds of these poor children, belonging to no less than 56 parishes, are lodged and nursed. The parish of St. James alone sends thither about 80. And when we consider the situation of the house, in a high and exposed situation, the very limited extent of the play-ground, the meagre dietary, and the huddled manner in which the infant paupers are put to sleep together, we cannot wonder at the dangerous state of body to which a large number of them are reduced, or the mortality which at times so strikingly prevails.

On visiting the place not long ago, Mr. Pettigrew found 17 of the 80 children belonging to St. James's labouring under serious illness—disease of one character—namely, a deranged condition of the digestive organs, evidently connected with a morbid state of the mesenteric glands.

The following description, when first published, struck many as being extravagantly overdrawn: but the subsequent inquest confirmed the principal facts; and the evidence adduced by Mr. Pettigrew, in the present publication, seems fully to warrant the veracity of his statement.

"The picture is almost too horrible to describe. I found the children with large heads, tumefied bodies, shrivelled and wasted limbs—mostly in a sitting posture, with their legs crossed; and I found upon inquiring of the nurse of the ward No. 9, in which the greater number of the sick were placed, that any change from this position occasioned them pain, and caused them to cry. The continued posture to which it is evident they have been accustomed has given to many a curvature of the bones of the legs; they have, in short, become ricketty from the want of exercise, and, I fear, an insufficient supply of wholesome nourishment. They labour under mesenteric disease in its various forms and stages. Some

* The Pauper Farming System: a Letter to the Right Hon. Lord John Russell on the Condition of the Pauper Children of St. James, Westminster, as demonstrating the necessity of abolishing the Farming System. By T. J. Pettigrew, F.R.S. Surgeon to the Charing-cross Hospital, &c. 8vo. pp. 43.

have discharges of blood and mucus; some from fifteen to twenty evacuations daily—all suffering from extreme thirst, and now, that under the judicious advice of the surgeon of the parish, they are taking proper nourishment, they become flushed upon receiving it. The state of their skin marks the condition of the internal organs—it is dry and scurfy—in many places, both on the head and limbs, particularly the lower ones, *ulcerated*. Languid and feeble circulation, and other marks of general debility, are strikingly apparent. Their glands are enlarged—their bodies swollen and painful to the touch. Some I found in the greatest state of prostration. The sight was truly appalling."

Now it is worthy of remark, that these poor little creatures were neither brought together from one locality, nor derived from one stock. As Mr. Pettigrew says, "It is quite clear that such an uniform character of disease among so many children, the offspring of different parents, must be the result of the particular manner in which these children have been nursed and maintained."

An impure atmosphere breathed over and over again by the wretched children, in their crowded apartments, is with reason presumed to be a primary cause of their sickly condition. It appears that in the male ward of Mr. Aubin's establishment, "there are no less than *ninety* beds; and that in each of these beds, according to the size of the children, two or three are placed to sleep. The congregation of so many children in one apartment, with the windows closed as they must necessarily be at night during the hours of rest, is highly improper and prejudicial to health. It is a fertile source of disease. Nearly 300 children sleeping in one room!"

But there is abundance of testimony regarding the state of these poor parish infants, in addition to that of Mr. Pettigrew. On the 3d of March last, Dr. Robert Lee visited Norwood, at the request of some of the parish authorities, and made a report to this effect—that of the 52 St. James's children, then at Mr. Aubin's, 15 only were in a tolerable state of health. "There were nine seriously indisposed, and the whole of the remainder were suffering from a deranged state of the stomach and bowels, with symptoms of scrofulous disease more or less apparent."

This statement was confirmed by Messrs. Braine and French, medical officers connected with the parish, and was speedily followed by a second report, in which Dr. Lee notices the probable causes of such a lamentable state of things.

"In endeavouring to assign the causes which produced this sickly condition of the children, I am fully aware of the difficulty of the task, and am ready to acknowledge that an opinion formed upon this subject with the greatest caution may nevertheless be erroneous.

"Although some of the children were reported to be ill in the month of September, yet I am inclined to believe that the exposed situation of Norwood, the severity of the weather during the winter, and the consequent crowding together of the children for longer periods than usual, and the deficiency of proper exercise in the open air, necessarily resulting from these unfavourable circumstances, have mainly contributed to impair the health of the children.

"The want of a regular Medical Superintendent of the Institution, and of a sufficient number of experienced nurses, has doubtless also contributed much to extend and aggravate disease among the children."

A passage or two may also be extracted from Dr. Tweeddale's report, made in September last, when there were eighty children belonging to St. James's parish at the Norwood establishment. Having noticed the respective conditions of the boys and the girls, he sums up in these words:

"By this you will perceive *that* FORTY, *or one-half* of the children ONLY *may be considered in a state of perfect health;* twenty are in a TOLERABLE *state*

of health, with the exception of the ringworm; five with scabies, whose healths are only slightly impaired; seven are suffering from mesenteric fever, accompanied with enlargement of the glands; seven are rickety from scrofulous constitution; and one chronic inflammation of the eyes from the same cause.

"*I am decidedly of opinion that most of these diseases may be fairly attributed either to improper or deficient nourishment*, and would recommend that the elder children should be supplied with meat daily, varying the quality, such as roast meat, either beef or mutton, corn beef or pork, boiled or hashed mutton, broths, beef-steak puddings," &c.

In the last paragraph Dr. Tweeddale, in our opinion, touches at the very root of the evil, and points out what, together with free air and wholesome exercise, must be mainly instrumental in the prevention, if not in the cure, of the loathsome maladies in question.

Dr. Lee, indeed, in his second report, does not attribute so much of the mischief to improper food, as the physician just quoted does: nay, he endeavours to exculpate Mr. Aubin and his institution from any such imputation.

"The disordered state of the digestive organs observed in many of them might lead to the supposition that there was something defective in the quantity or quality of their food; but the dietary stated by Mr. Aubin to be in use at his institution, is essentially the same as that in use at other extensive establishments which I have recently visited, and where I found the children in a state of good health."

But who can reasonably doubt how much the deficiency of a proper supply of nutritious food must be at the bottom of the evils suffered by these poor children, when he hears the miserable allowance vouchsafed for their support by the parish authorities? Will it be believed that the pauper-children of St. James's, Westminster, are actually farmed out at 4*s.* 3*d.* a head, per week, this sum being intended to cover all expenses, lodging, clothing, food, medical attendance, medicines, and all other necessaries, *burials* included!

To point out a better system for alleviating the miseries, and improving the management of these poor helpless infants, we are aware would be a hopeless task, if directed to the obtuse ears and hardened feelings of the persons who have the matter at present in their own hands. Yet we cannot close this short notice without suggesting—what, indeed, common charity dictates—that, for the management of these infant asylums there ought always to be procured, in the first instance, the steady and able services of a medical superintendent, and that he should be assisted by the well-tried and vigilant experience of proper nurses. Without this, and the disbursement of a liberal expenditure in the providing of good and sufficient food, and in securing a healthy situation for their residence, there can be no hope of any salutary change being effected—whilst a perseverance in the present order of things, *prejudicial ultimately to the true interests of the state, and revolting to humanity*, can only be attended with ruinous and fatal consequences.

KING'S COLLEGE.

We mentioned last week, that Mr. Green had resigned the chair of Surgery; we hear that he is to retire from private practice, but to retain his hospital, and his professorship at the Royal Academy. It is rumoured that Mr. Hodgson, of Birmingham, has been invited to become his successor at King's College.

Dr. Francis Hawkins has resigned the Professorship of Medicine, and is to be succeeded by Dr. Watson. By this arrangement a vacancy will take place in the chair of Forensic Medicine.

The chair of Materia Medica, vacant by the resignation of Dr. Bisset Hawkins, has not yet been filled up; but it is presumed that Dr. Gregory, who delivered the spring course of lectures, will be elected.

In the Council also some changes have occurred. Sir Henry Halford has retired, and Mr. Green has been nominated in his place.

COLLEGE OF SURGEONS.

Sir Charles Bell (not Mr. Green, as stated last week) has resigned his seat in the Council of the College of Surgeons, and has been succeeded by Mr. Babington.

The new building will very shortly be completed; soon after which, Mr. Owen, who has been appointed Hunterian Professor of Anatomy and Physiology, will commence an extended course of lectures in illustration of the preparations in the museum.

Mr. Stanley has been appointed Professor of Anatomy and Surgery.

MIDDLESEX HOSPITAL.

AMPUTATION AT THE HIP-JOINT.

On Monday, in last week, the operation of amputating at the hip joint was performed by Mr. Mayo, at the Middlesex Hospital. The patient's name is Hannah Allen; her case is described in Mr. Mayo's Outlines of Pathology, where the necessity of this operation is anticipated as a possible contingency. We understand that the patient has gone on most favourably, and may be considered out of danger. The details of the operation, and of the subsequent progress of the case, will be given in this journal, when a sufficient period has elapsed to enable us to judge of the result. There were present at the operation, besides Mr. Arnott and Mr. Tuson, who assisted Mr. Mayo, Mr. Stanley, Dr Clark, the Professor of Anatomy at Cambridge, and Dr. Valentine Mott, the celebrated surgeon of New York. Dr. Mott saw this patient a year ago with Mr. Mayo, on his former visit to London: he entirely concurred with Mr. Mayo as to the expediency of the present operation.

The amputation, which was commenced after the femoral artery had been tied, occupied about half a minute: not more than twelve ounces of blood were lost.

The operation was performed for neuralgia of a stump. It may be interesting to mention, that Sir Astley Cooper amputated an arm at the shoulder joint, for the same affection of the nerves of a stump, and that the patient was permanently cured. Mr. Bransby Cooper met with the like success in a case in which the hand had been amputated for neuralgia by Mr. Tyrrell: the disease returned in the stump, when Mr. Langstaff amputated the arm above the elbow: the disease again returning, Mr. B. Cooper amputated the limb at the shoulder-joint; the patient recovered, and has since been entirely free from suffering.

ROYAL ASIATIC SOCIETY.

Mr. Royle on the Productions and Resources of India.

At the general meeting of the society, on the 19th March last, the Right Hon. C. W. Williams Wynn, M.P. President, in the chair, the subject of the formation of a Committee of Agriculture and Trade was introduced. On the table was placed for inspection, in a series of cabinets, a very extensive collection, made by John Forbes Royle, Esq., comprising upwards of a thousand specimens of the vegetable and mineral productions of India, consisting of seeds, woods, barks, resins, gums, earths, metals, &c.

The Right Hon. Holt Mackenzie read an able paper, chiefly on the *commercial* resources of India: his remarks, however, he begged the meeting to consider as merely subsidiary to those of Mr. Royle.

Mr. Royle then addressed the society, and began by giving an account of the way in which his attention was originally drawn to the subject.

"I was written to, at first privately, and afterwards officially through Dr. Wallich, by my late friend, Dr. John Adam, then Secretary to the Medical Board of Bengal, to turn my attention to the *materia medica* of India, in order to ascertain whether the public service might not be rendered less dependent upon the supplies from Europe, either by substituting articles indigenous in the country, or cultivating exotics in the most suitable climates of the plains and mountains of Northern India.

"The subject proposed was sufficiently extensive, and the means of investigation apparently but limited. Dr. Fleming's valuable *Catalogue of Medicinal Plants and Drugs* contained but a small portion of those enumerated in the Persian catalogue called *Ulfaz Udwiyeh*, translated by Mr. Gladwin; and Sir Whitelaw Ainslie's extensive and very valuable work on the *materia medica* of India, having been compiled in the Peninsula, it was doubtful whether the same articles were procurable in the north as in the south, and, if so procurable, by what means they were to be obtained, as there was reason for thinking that the same names were not always applied to the same things. I, therefore, had recourse to the native works on this subject, which, I learned, were both numerous and comprehensive. But here the difficulties were still greater; for it was impossible to ascertain, with precision, what was generally described under an Arabic name, though assisted by its synonymes in Persian, Hindee, and frequently metamorphosed Greek, as well as by a

comparison with other articles, which, unfortunately, were in general as little known as those they were intended to elucidate.

"In this dilemma, the only resource was to get acquainted with things, in order to have an idea of the import of words. I, therefore, directed specimens of every article in the bazaars to be brought me, whether found wild in the country, or the produce of agriculture—whether the result of home manufacture, or of foreign commerce—whether of the animal, the vegetable, or mineral kingdom—whether useful as food or as medicine, or employed in any of the numerous arts which minister to the wants or comforts of man. I determined, as these were brought me, I would make a catalogue of the whole, with their various synonymes, inserting, whenever it was possible, their natural history and English names, so as to connect the knowledge of the west with the products of the east. It will require little to convince the Society, that when I commenced I was perfectly unconscious of the nature of the task I had undertaken, or the extent of the labour I had voluntarily incurred. That this was not of a trifling nature, will be evident by merely examining my catalogue of articles described in Persian works, many of which I was, of course, unable to obtain.

"Such was the origin of this collection in the remote station of Saharunpore, one thousand miles north-west from Calcutta, and almost the last of our stations in that direction. It was added to at Delhi and Agra, as well as in my progress down the river at Allahabad, Mirzapore, Benares, Patna, and completed as much as time would allow during my short stay in Calcutta.

"In coming before you, therefore, I cannot regret either the labour or time which both this catalogue and collection have cost, as they give me the advantage of recommending you, to do only that which I myself have done, and of shewing you, that if a single individual, with no exclusive attention to the subject, but while his time was fully occupied with medical duties, and the investigation of the natural history of the country, has been able to bring together so many articles from one part only of India, what may be expected from the attention of the Society, when turned to the three presidencies, as well as to other parts of Asia? It was to shew you that there is nothing visionary in this project—to convince you of the extent of the field of investigation—to speak to your eyes, while Mr. Mackenzie satisfied your understandings, that the collection has been laid open for your inspection, and not, be assured, for the purposes of display."

We can only give in the shape of extract some of the more remarkable passages which struck us in the perusal of this excellent address. Every part of it is indeed highly valuable and interesting; but we are obliged to have regard to our limits, as well as to a proper selection of the topics more particularly suited to the Gazette.

Valuable products of India.—It will, perhaps, be objected—and nothing is ever proposed to which objections are not made—that the majority of articles here exhibited are probably of little value. This may possibly be true; but I am very certain, that among them there are many very energetic as medicines, and others valuable in some of the most useful arts: indeed, it would be extraordinary if it were not so, considering the perfection of many of these arts in so early civilized a nation as the Hindus; where, from the processes being as simple as they are effectual, we may infer the intrinsic goodness of the materials which are employed.

Of this we shall be better able to judge when the more remarkable substances are subjected to examination, which may be done with greater facility than is at present apparent, either by taking them according to their uses as food or medicines, or their employment in the several arts; or, if we choose, by arranging them under the several heads of woods, barks, roots, seeds, &c.; or, preferably, according to their chemical nature, whether this be fecula, fit for food, as that afforded by the several cultivated grains, of which no where is the variety greater than in India; or in stems, as the sago-palms; or in the curcuma or arrow-root of India, yam, sweet potato, salep, or arum; saccharine principle, as in the sugar-cane and palm-trees; gums and mucilages, as in the acacias, and a variety of other plants; gum-resins, resins, varnishes, oils, either fixed or volatile, with fatty substances, as that yielded by the phulwa (*Bassia butyracea*) of Almora; together with the vegetable acids, as citric and tartaric; or the alkalies, as pearlash and barilla. If we want fibre fit, from its tenacity, for rope-making, we shall find a multiplicity of substitutes for the hemp, and, indeed, the hemp itself. If we want astringents for tanning, we shall find no lack of barks, woods, and berries, with the required properties. If we desire to aid the dyer with fresh tints in varying our ever-changing manufactures, those who have witnessed the rich colouring and gay variety of an Indian festival, or Hindú bathing ghaut, will require only their recollections to assure them that nature is not less bountiful in the east than elsewhere. If we add to these an examination of the several ores of the metals,

as iron, copper, and lead, together with the varieties of coal which we know to abound in India, and without alluding to the digging for diamonds, or the washing for gold, which would look more specious on paper than prove profitable in speculation, we shall find that some new mineral is yearly added to the list of Indian products; as magnesia at Madras, alum in Nepâl, and manganese at Ajmere: while we have yet to consider many valuable products from the animal kingdom, as hides, horns, elephants' teeth, wax, musk, &c., it might almost be said that India is yet a region of unexplored mines in all the kingdoms of nature. In inviting you, therefore, to explore so fair a field, I do so with the utmost confidence, that, if the vigour of our proceedings be at all commensurate with the variety of products, many years will not elapse before we have to congratulate ourselves on the result of our proceedings. If, while making the above classification, we were to arrange in the same way those substances which now form the commerce of the world, and place them in columns parallel to those which are the products of India, we should see at a glance the proportion which these bear to the whole; and, ascertaining where we had an opponent to rival, or a blank to fill up, obtain, with a knowledge of its present resources, an idea of the future prospects of India.

Rhubarb—Caoutchouc.—If we look to the commercial history of rhubarb, we find that the best, though produced in Tartary and Tibet, traverses all Asia, to be sold in Europe under the names of Turkey and Russian; while the Siberian frontier-town of Kiakhta is twice as far, even from the eastern limits of the true rhubarb country, as are the British territories in Upper Assam; while there is very good rhubarb within the Himalayas, and some of very excellent quality near its frontiers: is it not reasonable, therefore, to suppose that India may soon export some of the superior, instead of only the inferior, kinds of this drug? The recent extension in the uses, and, consequently, commerce, of caoutchouc, induces a hope that advantage will now be taken of the suggestions of Dr. Roxburgh, in his account of the caoutchouc of *Ficus elastica*, and other plants (*Fl. Ind.* iii. p. 541), as has already been done with respect to that of *Urceola elastica*; and, that as shell-lac, caoutchouc, flax, and rape-seed, have so recently become extensive articles of export, so it will be with other resins, more astringents, and not a few oil-seeds.

Rice—In connexion with rice, I may mention a fact which will show that even the most intelligent may make mistakes, when they will not take the trouble of understanding the subject in which they make experiments. Thus, a gentleman, wishing to improve the cultivation of rice in India, which he thought, from the specimens sent to this country, must all be inferior to the American, actually sent some bags of American rice to his correspondents in India, which, in the process of cleaning, had been *deprived of the embryo* of the future plant, for which the rest of the seed is only intended as nourishment during the process of germination. I will not detain you further with such instances, though these might be indefinitely multiplied; but I may adduce one from another kingdom of nature, where an equally inconclusive experiment was pronounced to be a failure. This was in the case of the cochineal insect, of which the *Grana sylvestra* variety was introduced from Rio Janeiro into Calcutta, and not the *Grana fina*, from Mexico. The insect was found fault with as being too ravenous, and its produce as very inferior in quality; and the inference has been drawn, that India is unsuited to the production of cochineal. If the Mexicans had been anxious to improve the breed of their horses, and had imported the vicious *tattoo* of India, instead of the noble Arab of the desert, the inferences from failure in their first attempts would have been equally legitimate,

Opium.—Opium, so long considered necessarily inferior, if it was East Indian, has been of late years produced of a very superior quality, as is evident by the quantities of morphia yielded by different kinds as given by Dr. Smyttan:—Bengal, 3; Malwa, 6; Turkey, 6½; and some from Bareilly as high as 8½ per cent. Specimens of all these should be somewhere deposited for the inspection of those interested in the subject, wherher physician, chemist, or merchant *.

---

* Since this paper was read, I have been informed by Mr. Harpur Spry, F.G.S., of the Bengal Medical Service, that the opium cultivation has been extended to the Cawnpore district; and the opium produced there "has been reported by the person appointed to test the drug, as the best quality of all that is received at Benares." "The cultivation was attempted a few years since, and proved a failure; but owing to the exertions and good management of Mr. Reade, the deputy collector, the Indian government is said to have derived a net profit, in the first year (1833), of 50,000 rupees; the second year, 75,000 rupees; and last year, the quantity was expected to be 200 maunds; and it will go on gradually increasing." At Saharunpore, still further to the north-west, I myself made some opium, in 1829, which was submitted by Mr. Mackenzie, then Territorial Secretary, to the Medical Board, of which one specimen was pronounced, "perhaps equal, but certainly not superior to," and others, "resembling in almost every particular," some of an improved quality made by Capt. Jeremie the previous season in Behar, which the Medical Board, however, had "no hesitation in considering equal, if not superior, to the finest Turkey that comes

Senna—Henbane.—That I may not be accused of dealing only in theoretical declamation, I trust it may be allowed me to bring forward a few instances where I have successfully reduced some of these principles to practice. Of these I will mention the *senna* as a tropical, and the *henbane* as a European plant, both which were cultivated in the Saharunpore Botanic Garden, and nearly in the same field; but the former, in the rainy season, and the latter, during the cold weather months. Both were subjected to experiment in the general hospital of Calcutta, when the late Dr. Twining pronounced the extract of henbane to be of "most excellent quality, and the senna leaves as "equal to the best he had ever seen." The last being an extensive article of commerce might be cultivated in every part of the plains of India, as Tinnivelly and Saharunpore are separated by a breadth of territory of 20° of latitude; and where the henbane was grown, other European herbaceous drugs might, no doubt, be cultivated with equal ease.

Tea,—black and green distinct Species.—The discovery of the tea-plant in Upper Assam, will, I hope, be allowed to be a strong confirmation of the theoretical grounds on which its cultivation was recommended in different parts of the Himalaya, both by Dr. Wallich and myself. I did so chiefly on the great coincidence in latitude, as well as in many points of climate, but principally in the great resemblance in the vegetation of parts of the Himalaya with that of the tea countries, as far as we are acquainted with these, and the finding in the former many plants which are not known to exist elsewhere, except in China and Japan. With respect to the tea, I may also add, that the opinion of Mr. Loddiges, Dr. Hooker, and especially of Mr. Reeves, which I did not hesitate to adopt, after examining the plants in Messrs. Loddiges' extensive nursery, of there being two distinct species of *Thea*, yielding the black and green teas, has been fully confirmed by Mr. Gordon's last visit to China, as may be seen in the March Number of the *Asiatic Journal*.

Climate of the higher regions of India.—As the diminution of temperature in the atmosphere is very gradual, according to elevation, so is the disappearance of tropical forms as we ascend up mountains: hence, we find such plants diminishing in number and size as we ascend either the Andes or the Himalayas. Their existence at considerable elevations may probably be favoured by the range of the thermometer being less on mountain tops than on plains, even where the mean temperature is the same; and, perhaps, the effect of the extremes of temperature may be less injurious when transmitted through a more rarefied medium. But in mountains under the influence of tropical rains, a peculiarity of circumstances occurs analogous to that so well described by Baron Humboldt in the Andes, as the region of clouds; so in the Himalayas, the thermometer does not vary ten degrees during three months, at seven and eight thousand feet of elevation; and even when rain does not fall, there is constant humidity, from the air charged with moisture in the heated valleys rising to and depositing it on the cool mountains. The cloudiness, at the same time, preventing the full influence of the sun's rays, and at night the radiation from a mountain ridge bearing but a small proportion to the mass of the atmosphere, comparatively little cooling takes place, and the thermometer is but a few degrees cooler in the morning than it was on the previous evening: so that the same equability which we have observed at the base of the mountains, is observed, from the operation of other causes, to take place at considerable elevations. This being combined with moisture, we have two of the characteristics of a tropical climate, and find that, in such circumstances, a less degree of heat is essential for the maintenance of plants otherwise indicative, though only annuals, of a tropical vegetation. Of these may be instanced one of the *Scitamineæ*, the family to which the ginger and cardamom belong, at as great an elevation as nine thousand feet, with balsams, bigonias, cyrtandraceæ, a Smithia, cassia, &c.: even a bamboo is found as high as ten thousand feet; but its annual stems are yearly levelled by the falls of snow, while the roots are protected by their subterranean situation from the great changes of temperature. We need not be surprised, therefore, that rice should be cultivated at such elevations even without the assistance of irrigation.

Variety of Indian productions.—Such are a few general views respecting the geography of plants in connexion with climate, and with reference to cultivation. Between the extreme points of a tropical and a polar vegetation, we might shew a series of gradations, and find an equivalent for each within the limits of British India: but these would lead into unnecessary detail; and the object has, perhaps, been sufficiently gained, if I have been successful in shewing in what way the distribution of plants is connected with the im-

into the market at home." It was on these grounds, and from the superior quality of the opium cultivated in the Himalayas, that I, two years since, published the opinion, that "if it were an object to make the best opium for the European market, there is no doubt that Malwa, and the north-western provinces, would be best suited for the experiment."

provement of the resources of a country, particularly when we wish to acclimate the productions of other climes in one like India, which embraces within its limits so great a diversity of climates.

Of this, even the most sceptical may be convinced, if it be considered, that, suited as are Ceylon, and the southern extremity of the Peninsula, for cinnamon, nutmeg, cacoa; and the coast of Malabar, for pepper, cardamoms, coffee, and teak,—they are not more so than are Bengal, and the lower provinces, for their rich cultivation of rice, indigo, and silk; with ginger, turmeric, long pepper, and betel-leaf, luxuriant bamboos, and the bread-like plantain, ever-useful cocoa, and slender areca. The northern provinces having a less rich soil and drier climate, may boast of their wheat, barley, and potatoes at one, and rice and sorghum at another season, as well as of their fitness, together with Malwa, Bundlecund, and parts of the Peninsula, for the production of cotton, tobacco, and opium; while sugar, numerous oil-seeds, and substitutes for hemp and flax, are produced in nearly every part. Almost every jungle is occupied by the lac insect, and a kind of kino is yielded by the dhak butea. The most barren hills afford olibanum, and the most arid-looking plains will nourish the gum secreting acacias, and the mouhwa, or bassia, of which the flowers are fermented into a spirit, the seeds expressed for their oil, and the wood valued as excellent timber. Even in the western desert, the lakes yield salt, and their shores are lined with plants, which are burned for barilla. The mountains, though their bases are lined with a tropical and unhealthy jungle, abounding in valuable timber, have, at certain elevations, a delightful climate, and productions analogous to European countries: here we may soon hope to see the tea-plants a thriving culture, and the hemp turned to useful account; and though the cold and bleak tops of these mountains, and the plains on the northern face, appear barren and unprofitable, here their lakes abound with borax, and their valleys with vines; and, in addition, we have spikenard and rhubarb from the vegetable, with musk from the animal, kingdom.

The thanks of the Society were unanimously voted to Mr. Royle, for his valuable communication: after which the meeting adjourned.

There are but two kinds of death—either that of the nerve-life (sensibility), or that of the blood-life (irritability).—*Hufeland.*

THE NEW POOR-LAW SYSTEM

OF PROVIDING

MEDICAL ATTENDANCE.

ITS INEFFICIENCY AND ABSURDITY DEMONSTRATED.

To the Editor of the Medical Gazette.

Sir,

After the various articles which have appeared in the Medical Gazette, and in other journals, on the subject of Medical Attendance on the pauper population, it may appear superfluous to direct the public attention further to the erroneous principles laid down by the Poor Law Commissioners for the formation of medical contracts; but having thought it expedient to draw up and submit to the members of a Board of Guardians recently formed, a statement of the evils complained of by the profession and by the poor, it has occurred to me that the desired object might be promoted by the publication of this statement in your journal, which, I am aware, occasionally meets with unprofessional readers. I may begin, then, by remarking, that the importance of the subject may not be duly estimated by those who live principally in London or in large towns, where the great number of hospitals and dispensaries open to all comers, renders it of little consequence who fills the office of parish surgeon. But in the country, where those who are unable to pay for medical advice have no such resource, it becomes of the greatest consequence, both to the pauper and to the rate-payer, that a proper appointment should be made. Cases have but too frequently occurred where heavy expenses have been entailed on parishes by the long continued illness or the death of the father of a family, arising from neglect on the part of the medical attendant; and this result may with justice be attributed to the short-sighted economy of the parochial authorities, who, to save a small sum in the doctor's salary, have appointed a person who has unworthily filled the office.

I think the principle "of retaining medical services by tender, and of throwing the appointments open to practitioners at a distance, and to the profession at large," cannot fairly be applied: for what are the qualifications necessary in the holders of such appointments? Doubtless, in the first place, skill and sufficient ability to treat the various diseases which will come under their observation; and so far, it cannot be imputed to the Commissioners that they have done wrong in directing the

acceptance of the services of any person who is legally qualified to practise. But with ability should be united integrity and a conscientious feeling, which will induce the contractor to afford to his poor patients all the assistance which the resources of his art will allow: for it must be recollected that the responsibility of a medical man is very small. No one but himself can judge whether he is giving the proper attentions to his charge, unless the neglect be so gross as to subject him to the jurisdiction of the coroner. If the flour or bacon sent in by the contractor be inferior to the sample, or be deficient in quantity, the circumstance will immediately become known to the master of the workhouse, or to the relieving officer, or to the Board of Guardians; but what attendance, or what medicines, are necessary to preserve the life, or to restore the health, of a sick man, is known to the medical officer only. Now what are the guarantees for the integrity and conscientiousness of a practitioner unknown in the neighbourhood, or of a young man from the schools, who has never been engaged in practice, and of whom it can only be known that he is a member of the College of Surgeons, or that he has obtained his license from the Society of Apothecaries? It may be said, that if, upon trial, he does not appear competent to the situation, he may be dismissed; but during the period of his probation, irreparable injury may be done.

Another erroneous principle appears to me to be that of appointing officers, on the ground "that the recent improvements in medical practice and education are such as in general to render the later diplomas certificates of a degree of competency equivalent to much practice on the part of those who have had an earlier education." This reasoning might be valid, did not the rapid communication of intelligence, by means of periodical journals and the constant publication of standard works, diffuse the knowledge of improvements in science and practice through the provinces, as fast as they are introduced in the schools and centres of instruction. I am sure there is no young man, entering on practice, but will acknowledge, that, however good his education may have been, there is something still wanting, which only experience and the constant habit of attending on the sick will supply.

I cannot understand the justice of the regulation by which it is ordered "that the aggregate charges for medical relief within the new Unions, shall not exceed the aggregate of the former expenditure for medical relief in the separate parishes now included in the Unions." I believe no one will assert, that under the old system the salaries have been excessive, whilst it may safely be said, that, in the great majority of instances, the compensation received has been quite inadequate to the duties performed. Indeed, the Commissioners themselves allege that medical men have been induced, by the smallness of their salaries, to have recourse to unworthy means, as the abuse of suspended orders, in order to increase their incomes. In the MEDICAL GAZETTE of 8th March, 1834, several remarkable instances are related, by Mr. Tomkins, of Yeovil, where the salaries received were grossly inadequate; and, indeed, such cases are to be met with generally in all parts of the country. I think no one will contend, that in these instances the remuneration is even nearly adequate; and yet, because such low rates have been accepted, no larger amount is for the future to be allowed. Is it probable that, in these parishes, proper attentions were paid to those unfortunate individuals in whose cases the evils of poverty and sickness were combined, and who lay entirely at the mercy of the parish doctor? Indeed, in some instances where practitioners have taken contracts at very inadequate rates, they have attempted to justify insufficient attendance and neglect by saying that they could not afford to pay greater attention for the sum which they received; an excuse almost equally discreditable to both parties to the contract, as it is most probable both parties were, in the first instance, aware of the inadequacy of the salary. "Why, then (it may be asked), did the medical man undertake the office, when he knew he should not be sufficiently paid for it?" And this brings me to the statement of the Commissioners, that "We may be sure that the medical practitioner will, in fixing upon his terms, do nothing which he considers will not, on the whole, be advantageous to himself." To this I answer, that, in most cases, the practitioner has only had a choice of evils, and that he has been compelled to adopt, not the line of conduct *most advantageous*, but that *least disadvantageous* to himself. True, there are many men in the profession who would, under these circumstances, fulfil their duty as honourably as if it were a source of emolument to them; but that is not the case with all; and is it wise, where the responsibility is so small, to expose them to the temptation which is offered by the impunity of neglect?

It appears to me that the making the medical districts identical with the districts of the relieving officers, will in many cases be productive of great inconvenience, without possessing any countervailing advantages. Cases of fatal delay have occurred from inability to send a special

messenger for assistance; and very frequently the greatest inconvenience is felt by the poor in sending for the necessary medicines. It will often occur that a medical man is in the almost daily habit of visiting a parish at a distance, whilst, perhaps, he scarcely enters another parish comprised in the same district once a month. In the parish where his visits are frequent on account of his private patients, not only will the attendance on the paupers be much facilitated, but he will be frequently able to forward medicines to the poorer class by the messengers sent by their more opulent neighbours. By this means much injurious delay, as well as serious inconvenience, will be avoided. On the other hand, when a pauper is ill in the parish which the medical officer does not frequent, his visit must be special; and the poor people, who can ill afford the two or three hours spent in the journey, will have to send repeatedly to the surgeon's house. Why, then, should the medical attendance on these parishes be united in the same person, merely because they are under the supervision of the same relieving officer?

In many places self-supporting dispensaries have been established; and their action will certainly be highly useful in supporting the independence of the labourer, and in placing the medical attendance on the poor on a footing more agreeable both to the patient and the surgeon; but these institutions are at present very limited in number, and in many places local obstacles exist to their establishment. But, even were they generally spread throughout the country, there would still exist a necessity for affording some parochial medical relief. Whatever may be the improvidence or the demerits of an individual, in case of sickness or accident he must be attended to; and if he does not obtain assistance from the parish, he must receive it from individual charity, or, as is now often the case, from the benevolence of the medical man. There will also be always a considerable class of persons, who will not be able to afford even the pittance required for a subscription to a self-supporting institution.

As, therefore, the office of parochial surgeon must exist, it is of great importance that the appointment to that office should be made upon right principles. Let, then, integrity, conscientiousness, and humanity, be considered in the appointment, as well as ability: let them even be placed in the first rank of qualifications, for of them every one can judge, whilst the scale of professional ability is in general but ill appreciated by the public. Let a remuneration be secured to the attendant, not liberal, but sufficient to compensate him in some degree for his trouble, and thus to strengthen his inducements to a full performance of his duty. Let the arrangements be made so as to suit as much as possible the convenience of medical men, and of the poor patients. If the arrangements are made on these principles, a great source of dissatisfaction on the part of the labouring population will be removed, a large and influential body of gentlemen will be conciliated, the operation of the new law will be thereby facilitated, and the pockets of the rate-payer will not suffer in the end.

In conclusion, sir, allow me to congratulate the profession on the efforts which have been made to establish a better system. I trust these efforts have not been made in vain. In the recent establishment of one or two Unions in this county, the appointments were not made by tender, but were distributed among the resident practitioners. The districts were not made too large, but were formed so as to suit the convenience of the surgeon and of his patients, and not that of the relieving officer. Let us hope, sir, that these are indications of an improving system, and that the public will discover at last "that a contract for talent and character must be formed on different principles from one for cheese and bacon."

I am, sir,
Your most obedient servant,
A Surrey Practitioner.

May 2, 1836.

CHANGES AT MIDDLESEX HOSPITAL.

Sir Charles Bell has resigned the office of Surgeon to Middlesex Hospital, preliminary to his going to Edinburgh. It is understood that Mr. Tuson will be elected Surgeon, and Mr. Alexander Shaw, Assistant-Surgeon, without opposition.

COLLEGE OF SURGEONS.

LIST OF GENTLEMEN WHO RECEIVED DIPLOMAS IN APRIL.

Thomas Davies, Hookwood, Surrey.
Thomas Jervis, Duke-street, Manchester Square.
Joseph Goldstone, Bath.
Joseph W. Swan, Carnew, County of Wicklow.
Edward King, Bath.
Thomas F. Tierman, London.
Arthur Tibson, London.
Robinson Elsdale, Lincoln.
Richard H. Meade, London.
Emilias S. Mayor, Bristol.
John M. C. Faircloth, St. Albans.
Thomas Charles, North Wales.
Richard Langworthy, London.

Richard M. Isbell, R. N.
John L. White.
Charles Malton, Seymour street, Portman Square.
John Hunter, Dublin.
Thomas Chesman, Sheffield.
R. Norton, Nailsworth, Gloucester.
Orlando Orr, Armagh, Tyrone.
J. B. Barsham, Cambridge.
Geo. Whitmarsh, Dalton, Wiltshire.
Joseph Collin, Saffron Walden.
Thomas Smith, Cheltenham.
W. P. Hoare, Hammersmith.
J. Jackson, Long Clawson, Leicestershire.
A. Cooper, Whetstone, Leicestershire.
Guernsey St. George Bowen, Terrington, Hereford.
George Eveleigh, New Kent Road.
George Back, London.
John Bond, Birmingham.
Richard Bird, West Stockwith, Notts.
Robert M. Lascelles, Stillington, Yorkshire.
John Welch, Hoibeach, Lincolnshire.
G. N. Dangerfield, Churcham, Gloucestershire.
T. G. Clifton, Worcester.
T. S. Ralph, London.
S. R. Jeffreys, Worcester.
Charles D. Steel, Scilly Islands.
James Cowherd, Kendal.
Thomas Truran, Exeter.
T. Dickinson, Thunderbridge, Yorkshire.
W. K. Jackson, Barbotthall, Yorkshire.
P. B. Ayres, Thame, Oxon.
E. Vorley, Carlton, Bedfordshire.
Henry R. Smith, Newark, Notts.
Thomas Stocks, Burgh, Lincolnshire.
J. Thompson, Dalton, near Richmond, Yorkshire.
A. J. Taylor, Morpeth, Northumberland.
W. Nichols, Hackney.
Henry R. Burton, Market Harborough.
J. R. Quick, St. Mawes, Cornwall.
H. Trevan, Port Isaac.
Joseph Parkin, Workington, Cumberland.
George F. Meadows, Ipswich.
William Elliston, Ipswich.
Frederick Heald, Wakefield.
W. Baillie, Jamaica.
William M. Cooke, Trinity Square.
W. S. Davy, Manilla.
Theophilus Clarke, Brighton.
Henry T. Tetlow, Liverpool.
S. Lamb, Stourport.
James Rowan, Belfast.
James Evett, Wellington.
J. Hutchinson, Newcastle upon-Tyne.
F. C. Finch, Greenwich.
Edward G. Baron, Hull.
John H. O'Neill, A.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

April 28, 1836.

Robert Saville, Sunderland.
William Macdonald, London.
Arthur Brisley Rye, Rochester, Kent.
George Flockton, Snettesham, Norfolk.
William Webb Dudley, Leicester.
George Leonard, Dursley, Gloucestershire.
Charles Henry Butler Lane.
William Henry Oliver.
Paul Parrott Vickerman.
George Viner Ellis, Minsterworth, Gloucestershire.
William Turner, Newcastle-on-Tyne.

WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

SATURDAY, MAY 14, 1836.

LECTURES ON MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

By Jon. Pereira, Esq., F.L.S.

Lecture XXXIII.

In our last lecture, gentlemen, we were examining the oxides of antimony. I described to you one method of procuring the protoxide, namely, by adding water to the chloride, and washing the precipitate thereby obtained with an alkaline solution. I propose, in the next place, to notice an impure form of the protoxide, commonly termed—

Glass of Antimony.

History and synonymes.—This substance was first described by Basil Valentine in the fifteenth century, in his "*Triumphant Chariot of Antimony*," where he says, "to make glass of antimony is a thing common and well known to many;" so that it does not appear he was the discoverer of it. It is sometimes termed *vitrum antimonii*; at others, *antimonium oxydulatum vitrifactum*.

Preparation.—Ground sulphuret of antimony is calcined by a gentle heat, so that part of the sulphur is burned off and converted into sulphurous acid, while the metal of the decomposed sulphuret attracting oxygen from the air, becomes antimonious acid; this, mixed with some undecomposed sulphuret, constitutes a grey residual mass (called *cinis antimonii*), which is to be heated in an earthen crucible. The antimonious acid gives out part of its oxygen, and becomes the protoxide of antimony: the disengaged oxygen, uniting with some sulphur, forms sulphurous acid, which escapes. The protoxide, with some undecomposed antimonial sulphuret and a portion of the silica of the crucible, fuses into a glass.

Properties.—It is met with in commerce as a glassy mass of a hyacinth red colour, usually transparent, brittle, tasteless, and easily fusible.

Composition.—Soubeiran has analysed it, and found its composition to be—

Protoxide of antimony	91·5
Silica	4·5
Peroxide of iron	3·2
Sulphuret of antimony	1·9
	101·1

Mr. Phillips analysed a specimen which contained *five* per cent. of silica.

Characteristics.—It may be recognised partly by its physical properties, and partly by digesting in hydrochloric acid, by which a solution of the chloride of antimony is obtained; this may be recognised by the tests presently to be mentioned.

Adulteration.—Gray says, that "some years ago, a druggist, being distressed and in the King's Bench prison, made a quantity of glass of lead, coloured it to imitate glass of antimony, and sold it for that article, before the fraud was discovered. Some of this glass still remains in the apothecaries' shops, to whom it was sold." To detect this fraud, boil the suspected glass in dilute nitric acid: we obtain, by this means, a solution which will give a white precipitate with sulphuric acid, if any lead be present.

Physiological effects and uses.—It is a violent emetic, and when swallowed in large doses acts as a powerful irritant poison, causing inflammation of the stomach, mortification, and death, in a few hours. You will find some examples of its fatal effects recorded by Frederic Hoffmann.

In this country it is never employed except in the manufacture of tartar emetic.

Antidotes.—The antidotes and general method of treating a case of poisoning by glass of antimony are the same as for tartar emetic.

Pulvis Antimonialis.

History.—A quack medicine has long been known under the name of *Dr. James's fever powder*; and having gained some repute, attempts have been made to manufacture it. With the cunning and disingenuousness of most quacks, Dr. James took good care to keep his process secret, and the specification lodged in the Court of Chancery, when he obtained a patent for it, is so worded that we cannot prepare his powder by it. Dr. Pearson having shewn that it was a compound of oxide of antimony and phosphate of lime, the antimonial powder of the London Pharmacopœia is intended to be an imitation of it. In the Edinburgh Pharmacopœia this preparation is termed *oxydum antimonii cum phosphate calcis.*

Preparation.—In the London Pharmacopœia we are ordered to prepare antimonial powder by throwing a mixture of 1 part powdered sulphuret of antimony, and 2 parts hartshorn shavings, into a white hot crucible, and to stir until visible vapour ceases to arise. The residuum is to be pulverised, and calcined at a white heat for two hours, and afterwards reduced to a very fine powder.

By the heat, the cartilaginous matter of the hartshorn is decomposed and burned off, leaving behind the earthy matter, (the phosphate of lime). The sulphuret is also decomposed,—the sulphur being volatilized, and the antimony oxidized, being first converted into protoxide, then into antimonious acid.

Properties.—It is a whitish, tasteless, and odourless powder, insoluble in water, and nearly so in acids.

Composition.—Here is the composition of *James's powder*, and the *pulvis antimonialis* of the London Pharmacopœia.

	JAMES'S POWDER.			PULVIS ANTIMONIALIS.	
	Pearson.	*Phillips.*	*Berzelius.*	*Phillips.*	
				1st sample.	2d sample.
Antimonious acid (called by Pearson and Phillips, peroxide)	57	56	66	35	38
Phosphate of lime	43	44	33	65	62
Antimonite of lime (soluble in water)	0	0	1	0	0
	100	100	100	100	100

Mr Brande says he has sometimes found as much as five per cent. of the protoxide of antimony present.

Physiological effects.—A difference of opinion exists as to the action of the pulvis antimonialis; some practitioners asserting that it is inert, or nearly so, while others ascribe to it various medicinal effects. Thus Mr. Hawkins gave one drachm morning and evening without any obvious effect; and the late Dr. Duncan has given a scruple and half a drachm several times a day, without exciting either vomiting or purging. Dr. Elliotson found even one hundred grains inert. It is not unlikely, however, that it may sometimes prove much more active, owing to the occasional presence of a portion of protoxide. Those who contend for its activity, say that it is diaphoretic in small doses, emetic and purgative in large ones. Some practitioners consider James's powder more active and certain in its operation than antimonial powder, and hence *pulvis Jacobi* is an ingredient occasionally met with in prescriptions: Dr. Paris, however, asserts it to be less active than the officinal imitation. If I were to judge from my own observations, I should say both are inactive, or nearly so.

Uses.—It is employed as a diaphoretic in fevers and chronic rheumatism.

Dose.—The dose usually stated is from three or four grains to about ten; but I have already mentioned that considerably larger doses may be given without any obvious effect.

Tartar Emetic.

History and synonymes.—This salt was first publicly noticed in the "*Thesaurus Medico-Chymicus*" of Adrian Mynsicht, published in 1631. Besides its more common appellation of emetic tartar, it has been known by various other names, such as *stibiated tartar, tartarized antimony* (its pre-

sent designation in the Pharmacopœia), *potash-tartrate of antimony*, and *antimonial tartrate of potash*.

Preparation.—It is prepared by boiling the bitartrate of potash and protoxide of antimony in water. The Edinburgh and Dublin Colleges employ the powder of Algaroth to yield protoxide; whereas the London College direct glass of antimony to be used. The boiled liquor is to be filtered, evaporated, and set aside to crystallize.

The theory of the process is obvious: half the tartaric acid of the bitartrate unites with two atoms of protoxide of antimony, to form a ditartrate of antimony, which, with one atom of tartrate of potash, forms tartar emetic.

Properties.—The crystals of this salt are, when fresh prepared, transparent; but they soon become white and opaque by exposure to the air: their primary form is a rhombic octahedron. The opacity of the crystals is owing to their efflorescing slowly: their taste is acid and metallic, and they have the property of reddening litmus. One part of the salt requires $12\frac{6}{10}$ parts of water, at 70°, to dissolve it, or $2\frac{8}{10}$ parts of water at 212°. The aqueous solution undergoes decomposition by keeping, like that of tartaric acid, and the tartrates generally. Alcohol will not dissolve it.

Composition.—This salt is composed of—

2 atoms tartaric acid, 66 × 2 =	132
2 atoms protoxide of antimony, 76 × 2 = ...	152
1 atom potash	48
2 atoms water, 9 × 2 = ...	18
	350

We regard it, therefore, as a double salt, in which the tartrate of potash is the basic, and ditartrate of antimony the acid constituent. On this assumption its name should be the *antimonial tartrate of potash*, and its symbol

$$(\dot{K}\,\overline{T} + \dddot{Sb}\,\overline{T}) + 2\,\dot{H}.$$

Characteristics.—It may be readily recognized as an antimonial salt, by passing sulphuretted hydrogen through its aqueous solution; by which we obtain an orange-red precipitate of the sesqui-sulphuret of antimony. By this agent (sulphuretted hydrogen) we may readily precipitate the whole of the antimony, leaving in solution bi-tartrate of potash, which, by evaporation, may be obtained in crystals. This is the easiest mode of analysing it, and one which was adopted by Dr. T. Thomson. 50 grains of tartar emetic gave him

	Grs.
Sesqui-sulphuret of antimony..	21·59
Bi tartrate of potash	28·69

There are other chemical characters possessed by tartar emetic, but the following are the most important: most vegetable *astringents* (that is, substances containing tannic acid) act on solutions of tartar emetic, and produce precipitates; thus the infusion of nutgalls, as also that of cinchona bark, have this effect, (if the solution of tartar emetic be sufficiently concentrated); the precipitate is the tannate of antimony. Decoction of oak bark is an exception, for it does not give rise to any precipitate, although it is powerfully astringent. The *alkalies* and their *carbonates* likewise occasion precipitates of the protoxide of antimony, but an excess of caustic alkali re-dissolves the precipitate, by combining with it, to form what we may term a *hypantimonite* of the alkali; for, under some circumstances, protoxide of antimony performs the functions of an acid; that is, it unites with basic substances, as in the instance before us. The *strong acids* (as sulphuric, hydrochloric, and nitric acids) occasion white precipitates of the protoxide of antimony, combined with a small portion of the acid employed. *Tartaric acid* occasions a precipitate of the bitartrate of potash. If some crystals of tartar emetic be heated, they decrepitate and carbonize, and before the blow-pipe readily produce metallic antimony. By calcining tartar emetic in close vessels, we obtain a pyrophoric alloy of antimony and potassium.

Physiological effects.—In the first place let us examine the *local* effects of tartar emetic. This salt is a powerful local irritant, but not a caustic; that is, it does not exercise any known chemical influence over the parts with which it is placed in contact. Its irritant properties may be regarded as of a peculiar or specific kind, at least if we are to judge from its well-known effects when applied to the epidermis. To observe these, we may sprinkle the powder over a plaster, or employ the salt in the form of solution or of ointment. By any of these modes of application we obtain an eruption of that kind of pustules, called by Dr. Willan, *phlyzacia*, and resembling those of variola or ecthyma. They are flattened when at their height, are surrounded with an inflammatory border, and have a central dark point. The largest are produced by using the powder sprinkled over a plaster; the smallest are developed by applying the solution. They are usually very painful. I am acquainted with no pharmacological agent producing an eruption precisely similar.

In consequence of the internal use of it, a similar pustular eruption has been

met with in the mouth, œsophagus, and small intestines, and white aphthous spots have been observed on the velum and tonsils.

We have further evidence of the local irritation produced by tartar emetic, in its action on the stomach and intestines. When swallowed in full doses, it gives rise to vomiting and purging, pain in the epigastric region, and after death there has been found redness of the gastro intestinal membrane. However, it would appear from the experiments of Magendie, that part of this effect should be referred to the specific influence which tartar emetic exerts over the stomach, independent of its direct local irritation, since the same symptoms, it is said, have been induced by the application of this substance to wounds.

Taken *internally*, in small doses, it increases the secretion and exhalation from the gastro-enteritic membrane, and of the liver and pancreas. Subsequently, other secreting organs become affected; the kidneys secrete more urine, the mucous membranes generally become moister, and sweating takes place without any very marked previous vascular excitement. These effects are more certainly and speedily produced by tartar emetic than by any other antimonial preparation. In somewhat larger doses, it excites nausea, and disorders the digestive process, and gives rise to an uneasy sensation in the abdominal region; and in still larger doses, violent vomiting is produced. Of all emetics, perhaps this creates more nausea in proportion to the vomitings, and I shall have occasion, presently, to point out to you the advantages and disadvantages of this fact, in practice.

In large doses, tartar emetic is capable of acting as a powerful irritant poison, and of producing death. This, however, is a rare occurrence in the human subject; and modern practice has satisfactorily proved that tartar emetic is not so poisonous a substance as was at one time imagined. Magendie states, that on opening the bodies of animals killed by it, he found the lungs of an orange-red or violet colour, incapable of crepitating, gorged with blood, and here and there hepatized. I confess I doubt the correctness of Magendie's conclusions; and my doubts have received a strong confirmation from the observations of Rayer and Bennett, who, in their experiments on the effects of tartar emetic on animals, never met with any pulmonary lesion. It has been assumed, from Magendie's statement, that tartar emetic has the same specific influence over the human pulmonary organs which he presumed it to have over those of animals; and in support of this opinion, a case noticed by Jules Cloquet has been referred to: it is that of a man who died of apoplexy, but who, within five days of his death, had taken 40 grains of tartar emetic. "In the lungs were observed blackish spots, very irregular, which extended more or less deep into the parenchyma of this organ." Furthermore, it is argued, unless we admit a specific influence of antimony over the lungs, we cannot well explain the beneficial effects of this remedy in peripneumony. In opposition to this view, I would remark, that in cases of poisoning by this substance in the human subject no mention is made of difficulty of breathing, cough, pain, or other symptom which could lead to the suspicion that the lungs were suffering; and in the case of poisoning related by Recamier, we are distinctly told that the thorax was sound. Besides, we should expect that if tartar emetic had a tendency to inflame the lungs, or at least to occasion pulmonary engorgement, that it would not be a very beneficial agent in acute peripneumony, unless we adopt the mode of reasoning used by the homœopathists. It would even seem that this substance must have an influence over the human lungs of an opposite kind to that supposed by Magendie; for in one case of pneumonia mentioned in Lepelletier's work, the use of from six to eight grains daily of it for the space of nine days, reduced the number of respirations from 50 to 18 per minute; while the pulse fell from 120 to 34 beats per minute. In the case of a child, six years old, the number of respirations was reduced in ten days from 84 to 24 per minute, and the pulse from 140 to 96.

I have already alluded to tartar emetic as a poison, and I ought to add, that the circumstance of enormous doses of this substance having of late years been exhibited with perfect safety, shows that this substance is not so poisonous as was at one time stated; but it would seem to be somewhat variable in its action in different individuals, or in the same individual, under different circumstances.

In Dr. Christison's work on poisons are several cases recorded in which serious and dangerous symptoms were produced by 20 or 27 grains of this salt; and in one case 40 grains produced death.

Now, contrast these with the cases given by those who employ tartar emetic largely as a therapeutic agent. Laennec, for example, says he never saw any ill effects from the use of it, although he has given 20 grains daily, and in one case, 40 grains in 24 hours. And you will find cases recorded in Bayle's "*Bibliothèque de Therapeutique*," in which several drachms have been exhi-

bited in 24 hours without any hurtful, but, on the contrary, with beneficial effects. However, it is to be recollected that in these cases the patients were suffering with active inflammation; to which circumstance, it is said, we ought to attribute this capability of bearing such immense quantities of so powerful a medicine. But this subject of *tolerance*, as it is called, of remedies, will be better discussed when speaking of the uses of this salt; and I shall, therefore, only add now, that this tolerance of large doses is not always referable to an inflammatory diathesis, for in Orfila's work on Toxicology, reference is made to a case noticed by M. Lebreton, in which six drachms were taken at once as a poison; oil was immediately administered, and the only ill effects were vomiting, which soon ceased.

Modus operandi. — 1. *Does tartar emetic become absorbed; and if so, are we to regard its remote effects as consequences of this?*—As this salt has not hitherto been detected in the solids or liquids of the body, the question cannot be answered in a positive manner; though I think analogy is much in favour of Magendie's statement, that it gets into the circulation, and in this way produces its constitutional effects. In the 13th vol. of the MEDICAL GAZETTE, p. 496, you will find a case strongly corroborative of this opinion: a young woman, suffering with pleuritis, took tartar emetic, and it was observed that her suckling infant suffered from its effects. The physician (M. Minaret) had the infant put to the breast in his presence; but the milk was no sooner tasted than it proved nauseating; the child showed every symptom of sickness and disgust, and threw up a quantity of coagulum. Another nurse was immediately procured, and the child soon recovered. M. Barré, however, denies that tartar emetic becomes absorbed, and has performed some experiments which appear to favour his notion, though they are not conclusive. You will find his opinions and experiments noticed by Rayer, in the *Dictionnaire de Médecine et de Chirurgie Pratiques*, at the article *Antimonie.*

2. *What are the remote parts affected by tartar emetic?*—In answer to this question, let us examine the different systems on which this medicine has been supposed to act.

(*a.*) *Alimentary canal.*—I have already noticed Magendie's opinion that tartar emetic acts specifically on the alimentary canal. His experiments led him to the conclusion that the stomach, duodenum, and rectum, were the parts particularly affected. Franc (a pupil of Professors Delpech and Lallemand, of Montpellier), on the contrary, thinks that it acts specifically on the duodenum and small intestines, but rarely on the stomach. The truth is, I believe, our facts are insufficient to enable us to decide for either of these opinions. The symptoms most frequently produced, and which indicate an affection of the digestive tube, are vomiting and purging: these are said to take place, not only when the medicine is swallowed, but also when injected into the veins, or into the windpipe; or when applied to the serous coats of the intestines, or to the cellular tissue.

(*b.*) *Respiratory organs.*—I have already referred to Magendie's statement that the lungs are specifically affected, and that death sometimes arises therefrom. Furthermore, I have noticed the diminution of the frequency of respiration in peripneumony.

(*c.*) *Circulatory organs.*—In many cases, tartar emetic reduces the frequency of the pulse: in one case, referred to by Trousseau, it fell from 72 to 44 beats per minute; and in another case, reported in the French Medical Gazette for 1833, it was reduced, in nine days, from 120 to 34 beats. These effects, however, are not constant, for in some cases no obvious diminution in frequency can be perceived. In some cases, the force and regularity of the heart's action are influenced.

(*d.*) *Nervous system.*—The great depression of the muscular power during the stage of nausea, the diminution of the frequency of the pulse, and the epigastric pain sometimes experienced under circumstances that almost preclude the supposition of gastric inflammation, have been referred to the influence of this medicine on the nervous system.

(*e.*) *Absorbent system.*—Some pathologists have referred the beneficial influence of tartar emetic in pneumonia, to the stimulus which this medicine gives to the absorbent system.

(*f.*) *Secreting organs.*—Increased secretion of *saliva* has been produced in dogs, according to Magendie, and in man, according to Drs. Griffiths and Jackson. Many authors have observed increased secretion of *urine*, as I have already observed. Lastly, every one is acquainted with the *diaphoretic* power of antimony.

3. *How does tartar emetic kill when administered in large doses?*—It is unquestionable that in many cases animals have been killed by tartar emetic, without there being left behind the least trace of inflammation; and, indeed, in some instances the death was too speedy to arise from this cause. I suppose, therefore, the death must be referred to an effect on the nervous system.

Uses.—I proceed now to speak of the uses of tartar emetic.

(*a.*) *As a local irritant applied to the skin*, we frequently employ it with advantage. I have already alluded to the three modes of using it for this purpose, namely, by sprinkling the powder over a plaster (a Burgundy pitch, or common strengthening plaster), — or mixed with some fatty body (spermaceti, ointment, or lard), and applied with the aid of friction, — or, lastly, using a strong solution of the salt. In delicate and irritable subjects, I always employ the latter method, as being the mildest and least painful. It is a point of some importance to determine whether the external application of tartar emetic ever produces constitutional or remote effects, such as vomiting and purging. Although I have prescribed it extensively, and have seen it used very largely by others, I never observed the least evidence of any constitutional disorder, and I believe this to be the experience of most practitioners. Rayer, however, says he has certainly seen colic and purgation produced in infants by the use of antimonial ointment; and Colson has observed the same in adults. I ought not to conceal from you the fact of a suspicion that now and then severe constitutional disorder is produced therefrom: nay, an infant of two years of age is said to have died after (and, as it was supposed, from) the use of an ointment containing tartar emetic. But these cases are so exceedingly rare, that I am disposed to believe the supposed ill effects must have arisen from some other cause. The local effects of these applications have at times been very violent,— even sloughing and death have occurred; but these cases are not frequent. I would caution you, however, against using these applications to wounds, leech-bites, or to blistered surfaces.

It is, I conceive, unnecessary to enumerate all the cases in which we employ tartar emetic as a cutaneous irritant, since the principles on which we use it are the same as for vesicatories. It has some advantages over cantharides; thus it is not liable to affect the urino-genital organs, though it has been said to have produced in children an eruption on these parts, but it arises from the child having conveyed by his fingers some of the ointment to the scrotum or perineum. When we wish to keep up long-continued irritation, it is, I think, a better application than a blister, and frequently much less painful. In chronic diseases of the chest, I sometimes order one part to be rubbed with the ointment or solution, and when the eruption appears there, to change the seat of application to some other part, and thus keep up the irritation by a succession of applications to different parts of the chest for several months. The following are some diseases in which this counter-irritant has been beneficially employed:—*In various diseases of the organs of respiration*, more particularly *hooping-cough*, in which disease it has been recommended by Autenrieth as a means of diminishing the frequency of the paroxysms and the violence of the cough; in *chronic catarrh*, *peripneumony*, and *pleuritis*, and even in *phthisis*. In the latter disease, when of a lingering kind, I have seen temporary benefit, such as alleviation of cough and pain, by the occasional use of antimonial frictions. In *laryngitis* also these applications are occasionally of great service. In *various affections of the joints*, especially chronic inflammation of the capsular ligament, or of the synovial membrane, hydrops articuli (particularly when connected with inflammation), and tumors of various kinds about the joints.

(*b.*) *A stimulating wash*, composed of one scruple of tartar emetic to an ounce of water, was proposed by the late Sir William Blizard, in the year 1787, to cleanse foul ulcers, repress fungous growths and venereal warts, and as an application to tinea capitis. A weak solution (as half a grain to the ounce of water) has been employed as a stimulant in chronic ophthalmia, and in spots on the cornea.

(*c.*) *As an emetic*, tartarized antimony has been injected into the veins, as I have already mentioned in a former part of the course. Now and then it has been used in the form of lavement, but the usual method of exhibiting it to excite vomiting, is by the stomach. *Injected into the veins* as an emetic, it has been employed on various occasions: in one case by Köhler; in two by Balk, and one by Gräfe (noticed in Dieffenbach's work, "*Ueber die Tranfusion des Blutes, und die Infusion der Arzeneien*,") and in one by Knoph. The cases being very analogous, I shall particularize one only, that of Köhler. A piece of beef tendon stuck (in the act of swallowing) in the throat of a soldier: the most violent symptoms immediately came on, namely, convulsions, swelling of the face, coldness of the extremities, feeble hoarse voice, cold sweats, and a small but very frequent pulse. Not being able to push the beef into the stomach by means of a probang, Köhler injected six grains of tartar dissolved in water into a vein of the arm. In half an hour vomiting came on, and the meat was expelled with great force, being thrown, it is said, to the distance of eight feet! Knoph used only four grains dissolved in half an ounce of water; Balk about a grain and a half.

Kæmpf has recommended a few grains of tartar emetic to be added to a common

clyster, with the view of exciting vomiting; but Rayer says he has frequently employed from six to twelve grains without producing either nausea or vomiting.

As before mentioned, the *usual* method of administering tartarized antimony as an emetic is by the stomach, in doses of one or two grains, commonly combined with ten or fifteen grains of powdered ipecacuanha. When we wish to *evacuate the contents of the stomach merely*, with the least possible disorder to the system, this salt is inferior to some others,—for example, to the sulphates of zinc and copper,—and hence these latter are preferred in cases of narcotic poisoning, since they occasion less nausea and depression of the system, while they excite very speedy vomiting. On the other hand, when we use vomiting as a means of making an impression on the system, tartar emetic is by far the best remedy for the purpose: hence, we resort to it when we wish to excite vomiting at the commencement of fevers, in croup, in ophthalmia, and other diseases in which this kind of medication has been found useful; for we can hardly suppose that the beneficial effects of emetics, in these cases, depends on the mere evacuation of the contents of the stomach. To promote the vomiting, warm liquids (as water or infusion of chamomile) are to be administered in the intervals.

(*b.*) *As a nauseant, to reduce the power of the muscular system*, tartar emetic is sometimes resorted to. Thus, in dislocations of the larger joints (the hip and shoulder), blood-letting and nauseating doses of tartar emetic are employed, to diminish the resistance of the muscles opposing the return of the bone to its natural situation.

(*c.*) *As a contra-stimulant, antiphlogistic, sedative, or alterative.* — Formerly tartar emetic was used only as an evacuant (emetic, purgative, or diaphoretic), but of late years it has been employed in certain inflammatory diseases, with the view of influencing the morbid action, independent of any vomiting or purging; nay, the occurrence of vomiting is regarded as an accident, and every care taken to avoid it. According to the particular theory entertained of its operation, the influence of the remedy has been designated; and thus some term it *sedative*, others *contra-stimulant*, or *antiphlogistic*, while a third party designate it *alterative*. We are indebted, I believe, to the Italian school for the introduction of this new mode of medication into practice, particularly to Rasori, Tommasini, Borda, and Rubini, though Hufeland has claimed it for his countrymen, Brendel, Schroeder, and Richter, while others give the credit to Dr. Marryatt, of Bristol.

As I have already explained to you, though very briefly, the doctrine of contra-stimulus, it is not necessary I should again discuss this subject, further than to remark that, whether true or false, we must admit that in some diseases patients better support certain remedial measures than in others. Thus in peripneumonia a larger quantity of blood may be abstracted than in cholera; and so far, indeed, the explanation given by the Italian school, of the capability of the system to bear enormous doses of tartar emetic during peripneumonia, accords with this fact. When we read the reports published of the use of tartar emetic in pulmonary and rheumatic complaints during the last few years, (of which Bayle in his *Bibliothèque Therapeutique*, and Lepelletier in his recent work on this substance, have given a good abstract), we are astonished that an increase in the dose of tartar emetic does not give rise to a proportionate increase of the evacuant effects. I have already alluded to the enormous doses which have been employed, some drachms even having been taken in the day, without producing any severe symptoms. Now, according to Rasori, this diminished sensibility of the system to the influence of tartar emetic arises from the peculiar diathesis which accompanies peripneumonia; consequently, if the theory be worth any thing, the susceptibility to the influence of the medicine should increase as the disease declines, a circumstance which Rasori declares is really observed. There is here, I suspect, an error, and that, too, of an important kind, in relation to the theory of contra-stimulus; for, as Laennec observes, "it is certainly true that after the acute period of the disease, the tolerance diminishes, or sometimes entirely ceases; but it is more common to find the patient become habituated to the medicine, insomuch that, during convalescence, and when he has began to use food as in health, he will take daily, without knowing it, 6, 9, 12, or even 18 grains of the tartar emetic."

In those cases in which tartar emetic has been employed with the most beneficial effects, neither vomiting nor purging have occurred. When *tolerance* (for so Rasori terms it) of the remedy is not gained, that is, when either vomiting or purging, or both, are observed, the beneficial influence of the medicine is usually much less obvious, although Laennec remarks he "obtained remarkable cures in cases in which such evacuations had been very copious."

There is a considerable number of interesting subjects connected with the use of tartar emetic in inflammatory diseases,

which want of time compels me to pass over. I proceed, therefore, at once, to notice the use of it in particular diseases. In *peripneumonia* it is one of our most valuable remedies, but will not wholly supersede the necessity of blood-letting, as some of the enthusiastic partizans of this medicine have asserted. After venesection, commence the use of one or two grains of tartar emetic every two or three hours, unless, indeed, there be much gastric irritation, in which case, the remedy had better be omitted altogether. Some combine opium with it, but the practice is not advisable in the first stage of the disease.

In *rheumatism*, tartar emetic has been declared a most efficient remedy by Laennec and others. Judging from my own experience, I should say it was a remedy of no great value; and you will find several late writers (Lepelletier and Rayer, for example) speak doubtfully of it.

Various other inflammatory diseases have been treated by tartar emetic with advantage—for example, *phlebitis*, *acute hydrocephalus*, and *ophthalmia* In *pleurisy* this medicine is not so beneficial as in inflammation of the substance of the lungs: according to Laennec, it assists in subduing the inflammatory action, but has no effect on the effusion. In *bronchitis* (both acute and chronic) I have, on several occasions, found it a very valuable remedy.

(*d.*) *As a sudorific.*—Tartar emetic is one of our most valuable diaphoretics, or sudorifics, being oftentimes available when other agents of this class are inadmissible: for example, in fevers and other diseases where we are desirous of producing diaphoresis, but which are accompanied with preternatural vascular action about the head, the use of those sudorifics (the compound ipecacuanha powder, for example) which contain a narcotic substance is objectionable; whereas tartar emetic may be employed with safety, since it has no tendency to increase the disorder of the nervous system. On the other hand, when much gastric or enteritic irritation is present, the narcotic sudorifics are generally to be preferred to tartarized antimony.

(*e.*) *As an expectorant* in various pulmonary affections, small doses of this salt are frequently employed with advantage.

(*f.*) *Injected into the veins.*—I have already alluded to the injection of tartar emetic into the veins in order to excite vomiting, and on this point I need not say more. But this operation has been resorted to for other purposes. Thus the elder Meckel injected two grains of tartar emetic, in a case of suspended animation from immersion in water. In some affections of the nervous system (for example, epilepsy and tetanus) also it has been tried. Further experience, however, is wanting to determine the efficacy of this kind of medication.

Administration and dose.—We rarely administer this salt *in substance,* though sometimes one or two grains, mixed with ten or fifteen grains of powdered ipecacuanha, are used to excite vomiting.

The best mode of exhibiting it is in the form of *solution.* In the London Pharmacopœia we have a solution in water, to which a little rectified spirit is added, to assist its preservation, and which is most absurdly denominated *vinum antimonii tartarizati,* since it contains no wine. This preparation was substituted for the old *antimonial wine* (made with sherry wine, and still kept in the shops), in consequence of its being found that druggists frequently used an inferior wine in its preparation, which, after a time, caused the precipitation of the oxide of antimony of the salt. Half an ounce of the Pharmacopœial solution contains just one grain of tartarized antimony. The dose of this solution varies according to the object we have in view in prescribing it. As an *antiphlogistic*, or *contra stimulant*, the usual dose would be from half to one liquid ounce, and some give much more than this; but it is better, I think, to use a stronger solution. As an *emetic*, from four to six or eight drachms; as a *nauseant*, I frequently give from one to two drachms, by which purging is also sometimes produced. As a *diaphoretic* one drachm will be found effective, if assisted by warm clothing; as an *expectorant*, about half a drachm.

As an *external* application, we use a solution of tartar emetic. To excite a pustular eruption in adults, I usually employ a saturated aqueous solution; but for children it should be weaker. An *ointment*, to produce the same effect, is prepared by incorporating one drachm of tartar emetic in powder with an ounce of lard.

Antidotes.—In poisoning by tartar emetic the first object is to evacuate the poison from the stomach. Generally we have only to encourage vomiting, by the copious use of warm bland liquids. The antidote is said to be tannic acid, and, therefore, solutions of any vegetable astringents containing this substance are recommeneded, such as decoction of yellow bark, of nutgalls, &c. Although some cases are recorded, apparently testifying in favour of the efficacy of yellow bark as an antidote, I confess I have great doubts of its value; in consequence of some experiments which were made some years since by Dr. Clutterbuck, and of which I was a witness. He found that 1 or 2 grains of tartar emetic rarely

failed to vomit, though given mixed with the powder or dissolved in the decoction of bark; and this occurred in very nearly 100 instances. Venesection is often required to reduce the gastro-enteritis. Opium is also a valuable agent.

Black or Sesquisulphuret of Antimony.

History and synonymes.—Black sulphuret of antimony was known in the most ancient times, being used by the Asiatic and Greek ladies as a pigment for the eyebrows. The practice, indeed, is alluded to more than once in the Old Testament (2 Kings, ch. ix. v. 30; Ezekiel, ch. xxiii. v. 40). This compound is also called *crude antimony*, and *sulphuret* or *sulphide* of *antimony*.

Natural history and preparation.—Sesquisulphuret of antimony is found native under the name of grey ore, in Hungary, in the Hartz, in France, in Cornwall, in Borneo, &c. The method of fusing it out of its gangue, so as to form the crude antimony of the shops, I described in the last lecture.

Properties.—It is sometimes found native in the crystallized state, the primary form of the crystal being the rhombic octahedron. The fused sulphuret of the shops when broken has the metallic brilliancy, a striated crystalline appearance, and a dark lead grey colour. It is insoluble in water, is odourless, tasteless, and fusible.

Composition.—It is composed of—

$1\frac{1}{2}$ atoms of sulphur	24
1 atom antimony	64
	88

It is rarely or never quite pure, usually containing other metallic sulphurets, as of lead, iron, or arsenicum. According to Rose, chemically pure sulphuret of antimony is a reddish brown powder. Guibourt detected $\frac{1}{96}$ part of sulphuret of arsenicum in some crude antimony of commerce.

Characteristics. —It fuses, is dissipated before the blowpipe with the smell of sulphurous acid, and the formation of a white vapour which covers the charcoal support. Digested in muriatic acid it gives out sulphuretted hydrogen gas, and forms chloride of antimony in solution, and which may be recognised by the tests hereafter to be mentioned for this substance.

Physiological effects.—For the most part it is an inert preparation, and may be given in doses of several drachms for weeks without any obvious effects. Introduced into the cellular tissue it had no effect, according to Rayer. It is, however, admitted, that in some cases, when swallowed, it excites nausea and vomiting. To account for these occasional effects, it is supposed, that so long as this sulphuret is unchanged in its chemical properties it is inert; but that it sometimes meets with acid matter in the alimentary canal, by which it is oxydized and rendered active. We must not also overlook the variable quantity of sulphuret of arsenicum which it contains. Guibourt has found, that by boiling crude antimony in distilled water he obtained a solution of white arsenic, which must have been formed from the insoluble sulphuret of arsenicum by the act of ebullition. One ounce of crude antimony yielded him $1\frac{44}{100}$ grains of arsenious acid. You see, then, that a decoction of native sulphuret of antimony is not so inert as some have asserted; nay, it may be more active than the solid sulphuret, owing to the change effected on the arsenical sulphuret.

Uses.—It is principally used for the preparation of other antimonial preparations, and ought not, I think, to be given internally on account of the uncertainty of its effects. But it has been employed, particularly in the form of decoction, in *chronic diseases of the skin*, and doubtless any efficacy obtained therefrom is referrible to the contained arsenic, which every one well knows is beneficial in skin diseases. To this substance, also, we ought probably to refer the effect of crude antimony in rendering the coats of horses smooth. In *chronic rheumatism* and *gout*, and in *scrofula* also, it has been recommended. On account of the sulphur present, it has been employed as an *antidote* in chronic metallic poisoning; for example, in poisoning from the mercurial preparations.

Dose.—The usual dose is from half a drachm to one or two drachms.

REPORT ON THE MEDICAL INSTITUTIONS OF IRELAND.

By Wm. P. Borrett, M.D.
Assistant Commissioner for inquiring into the state of the Irish poor.

(*Communicated by the Author.*)

PART I.—ON THE DISPENSARIES.

The dispensaries established in the counties of Kerry and Roscommon, and in the East Riding of the county of Cork, to which my inquiry was directed, would, if well situate, well supported, and well conducted, furnish an invaluable means of relief to the sick poor. There are, however, several objectionable points in the present system, which I proceed to notice

in the order and arrangement adopted in taking the medical evidence.

The first, and one of the most important points for consideration, is the *allocation* of dispensaries. Although, generally speaking, they occupy suitable positions, they are in some parts unequally distributed over the country, being either unnecessarily close together* and frequent, or scarce, and even entirely wanting, where the public convenience most requires them. Thus the district is circumscribed within a narrow compass, or vague and undefined, and extending a long way. For it is the custom to swell the subscription-list by receiving contributions from every quarter, without reference to the extent of duty imposed on the medical attendant, who is sometimes called upon to visit as far as 8, 10, or 12 miles from the dispensary†. The reason of this partially existing state of medical relief, (for which, it may be observed, there is a tax levied upon the country at large), as well as of seeking contributions so far off, is to be attributed to the present plan of allowing any number of subscribers to originate a dispensary where they please, and making the grand jury presentment to depend upon the amount of private subscriptions.

The law, as it now stands, leaves the selection of the spot to the subscribers, and hence it may be applied rather for their own accommodation than the public benefit. Some amendment of it is therefore required, by restricting the establishment of a Dispensary to certain localities and a certain population; and at the same time to make its establishment, under such circumstances, compulsory. It was the general opinion of the witnesses who were examined on the subject, that supposing it were in contemplation to map out the country into Dispensary-districts, a tract of *four* miles, or thereabouts, extending in every direction from the residence of the medical officer, might very well be assigned to his charge, having reference also to the population—diminishing the distance where the people are collected into towns and villages, and increasing it on the contrary in such parts as are thinly inhabited.

The *building* was in general a decent-looking commodious house, consisting of two apartments, one a surgery, the other a waiting-place for the patients; or a room was set apart in the rear of the house of the medical officer, with a separate approach. Occasionally it was hired of a subscriber at a high rent. It was seldom the property of the county, but the witnesses admitted this would be a better plan, for in that case, if they had fixed upon an eligible place, they might be sure of keeping it. But from the want of some such regulation, exceptions to this kind of building were not wanting. Thus at Oysterhaven, it was an out-house; at Ballyleague, a bed-room; at Innishannon, a small detached stable, in a lane off the main street; at Tulsk, a dismal filthy barn, in a state of dilapidation; and in several instances, the Dispensary was held in the shop of the medical attendant, or in a small room which also served as a residence for his assistant, or servant, or in a mere cabin*, consisting of only one apartment, with a partition run across it, without reference to situation, condition, or convenience of any kind.

Among the *medical superintendents* to the Dispensaries which I visited, there were two individuals who held no kind of license to practice, whether as physicians, surgeons, or apothecaries. Several were only qualified as apothecaries, and were without a midwifery certificate. But by far the greater number of them had received a respectable professional education, and were members of the Irish or English Colleges of Surgeons, or Graduates in physic of the Scotch Universities.

No specific qualification being required by law to entitle a person to hold a Dispensary-appointment, the determination of this point rests with the subscribers, who are in general anxious, as well for the sake of the charity as on their own account, to procure competent men, as the public appointment often leads to their becoming the medical attendants in the families of the subscribers. Thus at Dunmamony, a stranger had been preferred to other candidates personally known to the

* I met with an instance of this in the town of Maynooth, having a population under 2000. Some subscribers objecting to have a physician who did not reside in the place, recommended a practising apothecary of the town as medical superintendent to the Dispensary. The recommendation was disapproved of by others, and the parties not choosing to coalesce, separate presentments from the grand jury were applied for, and procured, and thus two Dispensaries were established and carried on together for some time, where one would have been sufficient. Occasional reference will be made in this report to other Dispensaries in the county of Kildare, as Clane, Newbridge, &c.

† It may be stated '*in limine*,' that whenever particular instances are not adduced in the course of these remarks, abundant proof is to be found in the medical evidence, to which the reader is referred.

* French Park, Clanmaurice, or Causeway, Kinnatalom, Glanworth, Cloyne, &c. were among the worst of this description; and at Clane, in the county of Kildare, the Dispensary was held in a wretched hovel, crumbling for want of repair, and rented at 10*l*. per annum of the medical officer. It was visited on one of the days of attendance, but the shutters were closed, and no patients waiting.

subscribers, because his testimonials were most approved of. Nevertheless this plan of private patronage has its disadvantages, and sometimes, especially when there are not many resident local gentry, persons not duly qualified for the office obtain the appointment. Hence it would be better if the law imposed some restrictions, which might ensure the selection of competent medical officers in every instance.

Some advance to such a security for a good appointment has been obtained by the amendment of the law as to *elections*. Now, in the event of a vacancy, public notice must be duly given, of the ensuing election. No person can vote at once on paying a guinea subscription: he must be a previous subscriber, at least of a year's standing, or he must become a subscriber for life. Before the law was thus amended, it was a common thing for a man who had a certain sum of money to expend, to make votes enough to ensure his election, by subscribing in the name of friends. Advantage was also taken of the occurrence of a vacancy to get up an opposition, and so recruit the funds of the charity at the expense of the contending parties. The existing law has put an end to these irregularities.

Non residence, which had become a common custom, has of late been disallowed in several places in the county of Cork, as at Black Rock, Watergrass Hill, &c., but I find it still tolerated at Glenville, Douglas, Glanworth, Donoughmore or Majounay, &c. In the latter instances the medical officers resided at a distance of three miles from the Dispensaries; in the first, at Fermoy, at a distance of six. In Kerry there was not a single instance of non-residence, while in Roscommon it was very common. It was so at Brideswell, Lecarrow, Tarmonbarry, or Ruskey, Tulsk, French Park, Lough Glynn and Croghan, and at Keadue also, till within a very recent period. These places furnish one half the number of Dispensaries in the county*.

The practice of compelling the medical officer to reside on the spot should be every where adopted, if it be the intention of subscribers to make the Dispensary of real service; for how can medical aid be said to be fairly placed within the reach of the sick poor, and least of all when immediate help is necessary, if the medical officer attends at the institution one day only in the week, as was the case at Lecarrow and Croghan, or even oftener, and is away the rest of the time at a distance of several miles. Ruskey is full eight miles from Strokestown, where the medical officer lives; Lecarrow nearly as far from Roscommon; and in the other cases of non-residence just cited, the distance is not less than from four to six miles. It must, nevertheless, be admitted, that, placed as these Dispensaries are, in remote and impoverished districts, it is scarcely to be expected that medical men of any pretensions will be found willing to come and live on the spot, so long as the highest salary attached to such an appointment is limited by the Grand Jury to 60*l*., which is the case throughout the county of Roscommon.

Where there is a non-resident medical officer, the onus of his *duty* is generally thrown on a neighbour, to whose Dispensary the patients resort in the absence of their proper physician; or they are left to shift for themselves till the next day of the Dispensary being open, which may not be before nearly a week's interval. In other places, on the contrary (so widely do the regulations differ), instead of appointing only one day in the week, the subscribers are not satisfied with less than daily attendance at the Dispensary, and this, too, where the medical officer resides close at hand, and is ready to give assistance in all cases of sudden illness or accident.

If stated days and hours were assigned, either two days in the week for four hours long, or three days for three hours, sufficient time would be allowed for the due discharge of dispensary duty, while opportunity would be afforded for visiting the poor at their own dwellings. At the same time it would be necessary to restrict the medical officer to the service of that institution which had been given him in charge. In some few instances there were two, and in one instance no less than four, such appointments held at the same time by one individual*.

In towns it was not unusual to find more than one medical officer, as well as an apothecary, attached to the Dispensary; but in the country parts the business of the apothecary devolved in general upon the medical officer, who was obliged to compound and dispense the medicines himself, or he delegated this duty to an apprentice, or journeyman, or even to a servant.

But the employment of uneducated and unprofessional persons was not confined to the manipulation of drugs; they were sometimes allowed to bleed and perform

* The medical officer of the Newbridge Dispensary resided at Naas, and of Donodea, at Clane; the first at a distance of six, the second, of three or four miles, from the Dispensary.

* The same medical officer was appointed to Glenville and Fermoy, to Magouney and Donoughmore, to Kildorrery and Glanworth, to Clane and Donodea, and to Selbridge, Lucan, Leixlip, and Maynooth Dispensaries.

the minor operations of surgery, and even to tap in cases of dropsy. The phlebotomist at the Cork Dispensary, a person of this description, had a salary of 20*l.*; and the servant at the French Park Dispensary, who was naturally enough very proud of his surgical skill, was anxious I should go with him and see a dropsical patient whom he had under his care, and had tapped repeatedly.

The determination of the *amount of salary* rests with the subscribers; but in no instance did I find they had carried it beyond what is reasonable; indeed, they seldom had the means of allowing adequate pay. Occasionally it amounted to 100*l.*, but it never exceeded that sum. It was for the most part considerably less, even falling below 50*l.* In the county of Roscommon it was limited by the Grand Jury to 60*l.*; but the witnesses who attended the examination at Castlerea, acknowledged that it was hard upon the medical officer to fix his stipend at so low a rate.

The uncertain amount of payment, as well as its inadequacy, was made the subject of grave and constant complaint. Instead of having a fixed salary upon which they can calculate, the medical officers seldom know from year to year what sum they are to receive for their services: it depends upon the amount of subscriptions and presentments*, alike fluctuating and precarious. Of late the act of parliament having been construed not to make it imperative upon Grand Juries to grant a sum equal to the private contributions, they have reduced the presentments in some counties, where, owing to the multiplication of Dispensaries, and the weight of the public burdens, it was thought right to take advantage of this recent interpretation of the statute. At the same time the subscribers are apt to fall off, because the custom of granting pound for pound has been discontinued; or they require to be so much importuned before they pay, that it becomes irksome and disagreeable to apply to them; and the medical officer, rather than do it, is in the habit of supplying the deficiencies from his own purse, taking upon himself the risk of being repaid his advances, so that the treasurer may receive the full amount specified in the declaration, and thus be enabled to obtain a proportionably greater grant from the county. But in spite of this precaution on the part of the medical officer (the propriety of which it is not the proper place here to consider), the funds had declined, and to such a degree in some cases, that the means of providing a salary were altogether wanting, and they barely sufficed for the purchase of medicines. Although it was to be expected, under such discouraging circumstances, that the functionaries would relax in their efforts, and neglect the trust they had undertaken, it was gratifying to see that the loss of pay, or non-payment, did not indispose them, for the most part, from attending to the interests of the charities: the medical officers gave their services gratuitously but unremittingly in several instances. Nevertheless, it is desirable that a fair and certain compensation should be given, so as to impress them with a consciousness of their responsibility; and in many places it is absolutely indispensable to secure the services of a salaried officer, where there is not a sufficient number of individuals in the neighbourhood capable of supporting a medical man independently of the emolument of office. As a general rule, the salary should be in an inverse ratio to the size and wealth of the place. It should decrease according as the opportunity is greater of acquiring private practice, and increase, on the contrary, as the inhabitants belong more to the labouring and lower classes. But it is to be apprehended that as long as the medical officer has to depend for his pay upon the chance amount of contributions, and to court subscribers, so long will he be disposed to consult the convenience of the rich before the necessities of the poor—that as long as he is unworthily paid, so long will his duty be inefficiently performed, and the Charity more or less inoperative to all good and legitimate purposes

Upon the whole the Dispensaries were well supplied with *medicines* of a good quality, obtained from druggists of established character, and judiciously selected. As much cannot be said as to the supply of surgical instruments, splints, bandages, &c. What few instruments there were belonging to the institutions were often unserviceable through rust; and the other articles were not uniformly provided, as they should have been in case of accident.

I had occasion to remark that those Dispensaries were furnished with but a moderate and scanty supply of drugs, in which it was the custom, after defraying their cost, to hand over the surplus funds to the medical officer in the shape of salary. If, however, the salary was fixed at a low amount, then medicines would be provided in a sufficient, nay sometimes in a superfluous, quantity. They became, in such instances, a heavy item in the expenditure for the year; but since vouchers for the payment of the druggists' bills were not always producible, having been either wilfully destroyed, or lost through care-

* See under these heads further on.

lessness, it could not be ascertained whether the entire sum had been applied to the purchase of medicines.

Occasionally the medical officer was allowed to charge a round sum for medicines;—a bad plan, as it gave him the opportunity (if disposed to make use of it) of substituting inferior articles, and so gaining the difference in cost between good and bad. Sometimes no distinction was made between the stock of private medicines for sale, and those belonging to the institution: or the latter sort were stowed away in the corner of a shop, kept by the medical officer, while those he had upon his own account were well appointed and arranged, and ostentatiously displayed, which led to the impression among the poor applicants, that they had better pay a something for a good article than put up with a bad one. But not only was the trick resorted to of giving the public clearly to understand from appearances, that if they wanted good medicines they must purchase them at the shop, but the fraud was committed of selling the medicines belonging to the Dispensary without putting the money thus obtained to the credit of the charity. I mention this fraud as having been detected, although but in a very few instances; I by no means wish to imply that it was common, or to cast any imputation of the kind upon the medical attendants in general; and I wish as much to be understood when I state, there was at times strong reason to suspect that the pharmacy had been dressed up for the occasion of the visit of the Assistant Commissioners, and drugs procured for exhibition, but which did not belong to the Dispensary.

Sometimes little else was to be seen in the shape of medicine than a large cask of Glauber salts, or numerous bottles of castor oil; the latter being much in vogue with the people: or there was a very scanty store in hand—in fact no more than could be contained in a small cupboard or press; and the nature of the establishment was only made apparent by a board, stating the days of attendance, posted up over the door or window. The more delicate medicinal preparations, recently brought into use, were met with in a few places, but not generally. Indeed, on account of their concentrated form and drastic quality, they are not well adapted to Dispensary practice: persons taking them require to be constantly seen by the medical attendant.

There is still another point connected with the pharmacy—I mean the deterioration of drugs, from want of proper care and keeping. At Freemont, Elphin, Maynooth, &c. the medicines were spoiling from damp; and, in some instances, not only were no pains taken to preserve them, but the room in which they were kept was in a dirty and slovenly state, or the building in a ruinous condition. This was the case at Tulsk Dispensary, where, owing to the wet dropping from the rotten thatch, or driving in through gaping chinks in the mudwalls, and the wretched condition of the interior, the few ordinary drugs which were found jumbled together in the drawers of a musty press, proved, upon inspection, damp and damaged. At Oyster-haven, the filthy outhouse, which was used for the Dispensary, contained scarcely a pound's worth of medicine. And at Ballyleague, with the exception of some half dozen shelves put in the corner of the room opposite to that in which the bed lay, there was no arrangement for the Pharmacy—no fittings-up of any kind, neither drawers, cases, nor counter—no apparatus for compounding and dispensing medicines—nor any instruments, weights, or measures. Of the pots and bottles with labels on them, which stood upright on the shelves, many were found, on inspecting them, to contain merely the mouldy remnants of drugs, whose virtues were gone long since, many more to be empty, and others again, where it was possible to recognise their contents, had been misrepresented by the inscriptions set upon them. Three or four packets alone, containing medicines of the common kind, were of a good description: but the greater part of such stock as the establishment possessed, lay strewn upon the ground—bottles, gallipots, jars, and other utensils, mixed with sundry parcels of drugs, lumber, and rubbish. Nevertheless the annual charge for medicines, upon an average of the last three years, amounted to little short of *50l.*, a sum sufficient for providing an excellent supply of medicines, but which, it would seem, had been applied in part, if not chiefly, to purchasing sundry jars of oil, vinegar, and molasses.

Much useful information, in regard to the statistics and the sanitary state of the districts, might be furnished by a register, to be kept at each medical station, accurately and fully drawn up, recording the number of cases admitted, with the names and residences of the patients, the nature of the diseases, the treatment, and the result. A document of this kind was insisted upon, but with a different intention, by the Grand Jury of the County of Cork, for each Dispensary. It was thought it would prove a check upon the medical officer, and afford some clue to the amount of relief compared with the cost of medicine. But it was fairly alleged by the medical men, that it was next to impossible, in the press of persons at times

attending at the Dispensaries, to enter the required particulars; and they were for the most part content with putting down a certain number of cases, when their duty was done, according to the best of their recollection. Moreover, as tickets were not constantly demanded, nor, when presented, regularly filed and kept, the vouchers were wanting to count and compare with the entries, or there were not the proper means of verification or of testing the truth of what appeared on the face of the books. Hence but little dependence could be placed upon the register, which was, to my mind, neither a check upon the occurrence of an abuse, nor any criterion of the utility of the institution.

One of the chief abuses of the present system is the diversion of the funds of the charity from its proper objects. When sickness and poverty combine in an individual, the joint affliction fulfils the condition requisite to entitle him to claim relief; but it is not the sick poor alone who obtain aid from the Dispensaries. It is a very common notion with servants that their masters subscribe on their account; and, as far as the lower class of servants is concerned, perhaps little objection can be made; but the case is different with upper servants. At Castletown Roche, I was told of housekeepers and ladies' maids being driven up to the Dispensary, and substantial yeomen riding up, booted and spurred, and demanding relief in the name of their landlords, whose displeasure and the withdrawal of whose subscriptions they threaten if their applications are not attended to. "I was sent for," said the assistant medical officer of the Kilworth Dispensary, "to attend the wife of a nobleman's shepherd, who has a salary of 40*l*. or 50*l*. per annum. She was in labour of her first child. I remained in attendance the greater part of two days, and made, first and last, a dozen visits. No pay was offered me, on the ground that if they had asked for a Dispensary ticket of the secretary, or the agent, they would have obtained it. "This," he added, "occurred five months ago, and I was called only last week into the country, a distance of nine miles, to visit a Dispensary patient who rented a snug farm (about 40 acres), and was well able to pay." He also stated a third instance, in which a respectable farmer, seven miles off, was visited twice by himself and thrice by his colleague, upon an order of his landlord on the Dispensary. Similar instances of gratuitous relief improperly procured will be found, upon reference to the medical evidence, to be by no means uncommon.

It is absolutely essential to the right working of Dispensaries, that this abuse should be done away with. It is one of the very worst features of the present system. It has been carried to such an extent that subscribers have been supplied, through fear of disobliging them, with medicines for their dogs, horses, and even private families, at the expense of the charity. They have even gone further, and procured medical advice for themselves, as well as medicines, gratis *. True it is that the poor have access to the Dispensaries, but it is equally true that others, as in the cases just cited, assert their claim to assistance, who are any thing but proper objects for it: and thus these charities must, in some degree, be considered as established, not solely with a view to affording medicine and medical aid to the sick poor, but also for securing professional attendance for the domestic servants, tenants, and dependents of all kinds, of the gentlemen who contribute to their support. The subscribers cannot lay claim, therefore, to credit in all cases, on the score of being influenced by charitable motives alone: they must be regarded in the light of mutual insurers, or contributors to their own convenience and advantage. But besides being a gross abuse in itself, this kind of imposition upon the charity presses hardly and most unfairly upon the independent and industrious practitioner of medicine. If he resist it on the one hand, he runs the risk of giving offence to the subscribers, whose good opinion he is of course anxious to conciliate; while, if he yield on the other, it makes him the *drudge* of the place, debars him from acquiring private practice—and for what? for a yearly stipend of a few pounds—and entails upon him, at the same time, a most laborious, troublesome, and thankless office.

In general it was necessary to obtain an order for the aid of the institution. This is required with the view of inducing persons to become subscribers, by making it their privilege alone to recommend to the charity; and sometimes, as a farther inducement to raise the subscription, the number of orders allowed is made proportionate to the sum subscribed: but such a plan is open to objection. It sometimes happens that medical help is quickly wanted, and there is no subscriber at hand; or if the number of tickets is limited, he may have already distributed as many as he is entitled to; or there may be an un-

* I was told of a medical man being sent for to the house of a subscriber to see a servant, whom he found in bed, but ailing nothing. He was requested, however, on leaving the house, "just to look at one of the children, who was slightly indisposed." The child was seriously ill, and he gave his advice, but his Dispensary salary was considered to be the proper fund for remuneration.

willingness on his part to assist the applicant, or, what is more probable, he may not like the trouble of it. In places where there was only one subscriber resident on the spot, he has been known to be called upon to issue more than fifty tickets in a morning: and as such a system opens the door to annoyance, so also a market is sometimes made of the patronage incidental to the subscription. If the subscriber is a shopkeeper, he may turn it to account by stipulating that all those to whom he gives tickets should deal with him, and in other cases a like advantage may be secured. Hence it would be well to consider whether the formality of obtaining an order, which may thus be made a means of abuse, may not be entirely abolished.

In that case, the Dispensary would be open to all the sick poor belonging to the district: they would have free access to it, and be able to get relief upon personal application, leaving a discretionary power with the medical officer to withhold it from such as he conceived to be improper objects for the charity. Such a plan, however, should be subject to the control of the managing committee, with whom the adjudication of all matters in dispute should rest. If the case be a doubtful one, assistance might at first be given, and information as to the condition of the person obtained for the purpose of submitting it to the Committee. It would not be long before the medical officer would learn to discriminate between the deserving poor and those who are not in necessitous circumstances. Still it would be necessary, for the protection of the poor patients, that the medical officer should at all times be responsible to the Committee for the proper discharge of his duties.

Domiciliary attendance is an essential point to be provided for in a well-regulated Dispensary: but it would be to impose much too onerous a task upon the medical officer if he is to be at the beck of every applicant for relief, who may not like to take the trouble of waiting upon him. The plan of visiting *out-patients* can only be recommended under certain limitations. A visiting ticket might be required, the issue of which should remain with the subscribers, or the Committee, and be confined to such patients as they believe to be unable to attend the Dispensary.

The possession of this privilege, in addition to a vote in the election of officers, might be a stimulus to some persons to subscribe; and it would not entail any unreasonable degree of trouble upon the medical attendant if, at the same time, a small ward were annexed to his Dispensary, to which he could transport the worst cases,—an accommodation * which I would strongly recommend where there is not an hospital near enough to be of service, taking care that, when a visiting order is presented, the case be properly attended to.

With reference to *vaccination*, I found that although its protecting influence upon the constitution was a principle acknowledged by the medical men whom I saw, and who were almost unanimous in declaring that it seldom failed to mitigate and modify an attack of small-pox, if it did not wholly succeed in preventing it, the practice was but little in accordance with such views. Vaccination was not regularly performed, owing, it was said, to the strong prejudices of the people against it, and the difficulty which was found of keeping up a supply of vaccine lymph, and in the neglect of the mothers to bring the children back for medical inspection at the proper time, after they had allowed them to be vaccinated. But the means taken to counteract the prevailing notion against vaccination were not likely to have any effect; in general it was discontinued, or it was left to the apothecary to vaccinate, and he made a charge for doing it.

The trade driven by professed inoculators was another great drawback to the introduction of the cow-pock. These men perambulate the country, carrying with them a supply of the infectious matter of small-pox, and ready to inoculate even for the price of a meal. The magistrates sometimes interfered to put a stop to a practice so replete with danger to the community; but for the most part it passed unnoticed and uncontrolled: it had even the sanction of medical authority in one or two instances which fell under my notice. At Aghada Dispensary the medical officer was accustomed himself to inoculate with small-pox, which he declared he had done successfully,—meaning, that he had had the good fortune not to lose a case. But at Doneraille several children died the preceding year, the subjects of small-pox artificially produced, not by itinerant inoculators alone, but also by an apothecary of the town. And the servant attached to the French Park Dispensary (whose handyworks I have had occasion to notice under a former head), told me he had under his care, at the time of my visit, between forty and fifty children, in town and country, whom he had inoculated with the small-pox; so that he kept the disease for ever rife in the neighbourhood. No objection to his doing it was taken by the medical officer or sub-

* See latter part of Report upon the Dispensaries.

scribers, and no attempt made to introduce the cow-pock. I went with my informant to see two little patients whom he had inoculated the week before. One had taken the disease mildly, the other was alarmingly ill. My guide was at a loss to know what to make of the case. "He had never," he remarked, "known one take on so before—he was always lucky." It is bad enough when low and ignorant individuals are allowed to take advantage of the prejudices of the people and turn them to their own account; but how much worse when it is done by paid and accredited agents connected with public charities. It were better that these institutions should cease to exist, than that existing, they should work evil instead of good to the community.

In several instances which came under my notice in inquiring into the qualifications possessed by those who held dispensary appointments, I found that they had not attended to the study of *midwifery*; and yet, notwithstanding their neglect of this important branch of medical education, and their incapacity, they were sometimes obliged, from the force of circumstances, to undertake the practice of it, as when settled in remote rural districts, and being, perhaps, the only medical men in the way. Sometimes, but rarely, it was represented to be a line of practice which they did not choose to follow, when of course the usefulness of the charity was much abridged by its not possessing the means of rendering any assistance to puerperal women. It was the custom, however, and in general incumbent upon the medical officers, to attend in all cases of difficult and dangerous labour; but it was a common complaint, that they were not applied to till it was frequently too late to be of service. This they ascribed to the ignorance of the midwives, who are not sensible of the alarming condition of their patients, or are too jealous of the medical practitioner to call him in to their cases.

There were only a few certified midwives in the districts which I visited: they had been sent to the Lying-in Hospital at Dublin at the expense of the county; but the greater part had copied errors of practice from one another, or commencing as nurses, had boldly entered upon the province of midwifery. Repeated instances were adduced, in the course of my inquiry, of severe injuries both to mother and child, and permanent disabilities, which had been occasioned by their ignorance or want of skill—by their meddlesome and mischievous practices.

Impressed myself with the necessity of providing against an evil so generally deplored, and yet so prevalent, I would suggest, that all persons should be prohibited from engaging in the practice of midwifery who do not hold a certificate signed by a lecturer on midwifery in a medical school, or a medical superintendent in a lying-in charity, and countersigned by a magistrate or some other public functionary *.

In Ireland, where the means of the poorer classes are so miserably low that they cannot at times procure the common necessaries of life, it is highly desirable that *nourishment*, as well as medicine, should be supplied during sickness. The expense and abuse, which seem almost inseparable from such a plan, are the chief objections; but they are more than counterbalanced by the certain amount of good which would flow from the introduction of this great auxiliary means of affording relief with the administration of dispensaries.

Sickness may be simulated, and an attempt made to get alleviation for the cravings of nature, by pleading its infirmities; but besides that, when proper vigilance is used, the imposition is easily detected, it would be a sufficient check against the abuse to withhold, in a suspected case, other aid than that of medicine.

Neither would the relief which it is proposed to give, in the way of nourishment, be attended with a heavy expense. Any undue excess in the distribution of it might be controlled by the committee; and it should be confined to certain particulars of diet, as diluent and demulcent drinks, broths, wine, &c. which form part of the medical treatment, and are essential to its success. Medicine, without adjuvants of this kind, is of doubtful advantage; and although prodigally administered under the present Dispensary system, and sought for with avidity by the lower classes, among whom a taste for physic has been created by the ready opportunity of getting it, drugs constitute of themselves but a slender means of real relief. Their remedial effects are counteracted by the unfavourable circumstances of the patient, especially in regard to diet. Potatoes, the staple food of the Irish people, are highly injurious in dyspeptic complaints, of which they are indeed a chief exciting cause †, and in all cases attended with vomiting; and yet the poor, whether ill or well, are obliged to have recourse to

* See, in connexion with this subject, a letter lately addressed to the Editor of the MEDICAL GAZETTE, by Dr. F. Borrett, of Norwich (last No., p. 225).

† See latter part of Report upon the nature and cause of disease.

them. Many diseases, which would be made light of in the house of the rich man, prove, on this account, fatal among the poor; while the convalescence is prolonged and the proneness to relapse increased tenfold by the want of suitable and nutritious sustenance.

If this description of relief came within the scope of a Dispensary—if part of the money which is now sometimes extravagantly applied to the purchase of medicine, were laid out in supplying oatmeal, pearl barley, rice, &c.—or if there was any charitable society in the place for the distribution of such nutritious articles, with power to the medical officer to give an order—his means of doing good in the exercise of his vocation would be greatly increased, and the chance of recovery improved in numerous instances. A charity of this kind was established at Bantry by a benevolent individual, who was struck with the sight of a sick poor man lying near the chapel, unable to purchase even a little drink. Its first object is to relieve those who are labouring under sickness, and, if the funds allow it, the aged and infirm come in next for a share.

[To be continued.]

CASE OF

REMARKABLE DISLOCATION OF THE HIP AND KNEE JOINTS.

AMPUTATION—RECOVERY.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following case of sufficient interest, you will much oblige me by publishing it in an early number of your journal.

I am, sir,
Your obedient servant,
THOMAS BRITTAIN,
House Surgeon.

Chester Infirmary,
April 28, 1836.

Henry Duke, æt. 22, admitted into this hospital, February 4, 1836, under the care of Mr. Bagnall. He is a strong and muscular man, but of scrofulous habit, having the old scars of scrofulous sores on his neck and different parts of his body; has also been given to intemperance.

Has dislocation of the left hip backwards into the ischiatic notch, and also dislocation of the right knee. The tibia, upwards, on the anterior part of the femur, and the condyles of the femur, plainly felt among the muscles of the calf of the leg. The limb shortened four or five inches. The leg and foot swollen and cold; all circulation below the knee stopped. There are no marks of external contusion on any part of the body.

States, that whilst he was standing over a large boiler, the lid, which is nearly a ton weight, was suddenly hoisted to the top of the building; it fell, and knocked him down; but cannot say positively upon what part of the body it struck him; thinks it was upon the head.

The knee was easily reduced by gradual extension, by means of the pulleys, in a very short time, and was retained in its extended state by means of splints placed under the joint and secured by roller. The hip was also reduced easily in a few minutes by the pulleys, in the manner directed by Sir A. Cooper. Owing to having great pain, he took opii, g. ij. immediately. Ordered cold evaporating lotion to the knee.

Vespere.—Is in great pain.

Sumat Morph. Mur. gr. ss. stat.

Feb. 5th.—There is great swelling about the knee, and pain extending down the leg towards the ankle; no pain in the hip.

Appl. Hirudines, xiv. gr. Cont. Lotio. Sumat. Pil. Calomel, i.; Coloc. g. x. st. Haust. Sennæ c. postea.

6th.—The bowels have been moved once. Tongue loaded. Still pain down the leg, and about the ankle.

Repr. Hirudines et Haust.

13th.—The leeches have been repeated three times since last date, and the cold wash continued. The knee is now nearly its natural size, and little or no pain. The hip is perfectly free from pain, and has been since the day of the accident. There is great heat, redness, and swelling, of great toe, and inner side of the right foot (the side on which the knee was dislocated).

Hirudines, vi. parti. Lot. frigid postea.

March 1st.—Have been absent from home since last date, and no notes have been kept of the case. He has taken diaphoretic and anodyne medicines, with calomel at bed-time. There are now two or three superficial sloughs

down the outer side of the right leg, between the knee and ankle; lividity of the great toe, which is quite cold, but to his own feelings it, as well as the entire foot, feels very hot and painful. The foot is hot and red. There is a large abscess under the ham.

Catapl. commune. Lot. frigid pedi.

3d.—The abscess in the ham was opened this morning, and eight or ten ounces of thin reddish-coloured pus evacuated. The sloughs on the leg separating; the second toe has now become livid; the foot still continues hot and painful. He is slightly jaundiced; bowels open; urine high coloured.

Ordered a pint of Port Wine daily.
Mist. Quininæ, ℥i. (gr. i.) ter die.

8th.—Constitutional symptoms relieved; yellowness nearly gone; lividity has extended to all the toes; great discharge from the abscess in the ham; great pain in the knee and foot; the sloughs remain stationary,—no attempt at granulation under them. At a consultation held this morning, it was deemed advisable to amputate the limb, as the only means of saving his life.

Operation performed by Mr. Bagnall, about half-past 12. The common circular incision made about half way up the thigh. Bore the operation well; much venous blood lost. A great number of vessels required ligature (twelve or fourteen). Stump dressed lightly. It is useless detailing the after-treatment; suffice it to say, that the stump healed by the first intention, with the exception of the part the ligatures came through, which was perfectly healed, and the patient walking upon his crutches in the garden at the end of the third week from the operation.

I examined the limb after its removal, assisted by my friends, Dr. Edwards and Mr. Hanmer, surgeons of this city, when the following appearances presented:—

The toes in a state of mortification. Three superficial sloughs on the outside of the leg, one immediately above the tarsus, another half way up the leg, and a third near the head of the fibula. On making an incision through the skin and cellular tissue, the latter was found generally diseased, and in several places sphacelation was commencing.

The abscess which had been opened in the ham was found to be very extensive, having burrowed underneath the fascia to the anterior part of the leg, nearly as far as the ankle; it contained a large quantity of thick, reddish-coloured, unhealthy pus; from this abscess there were two openings into the joint, one in the ham, and the other anterior to the insertion of the biceps: the edges of these openings were jagged and uneven. On tracing the course of the artery, which had been previously injected, it was found to be obliterated, from just below the point where it gives off the superior articular arteries, nearly to its bifurcation into the anterior and posterior tibial arteries; the *nerve* for this distance also was slightly enlarged, and firmer than natural, having a cord-like feel, the whole being so closely connected by dense cellular tissue as to be scarcely separable. The attachments of the muscles were all perfect, and did not appear to have been lacerated. The superior articular arteries were not enlarged. With respect to the joint, there had been a complete disruption of the crucial and posterior ligaments (the lateral ligaments on both sides perfect): the anterior crucial ligaments had been absorbed, but the posterior crucial ligaments and the posterior ligaments were united into one band. The synovial membrane was healthy, with the exception of a slight degree of roughness near the patella; the semi-lunar cartilages, as well as the cartilages on the ends of the bones, were healthy. There was no fluid in the joints.

Remarks.—The above case is interesting in many points of view; firstly, as regards two such rare dislocations occurring together without any external marks of violence; dislocations which, when occurring separately, require great violence to produce them. Secondly, as regards so complete a dislocation of the knee itself, an accident of very rare occurrence; it is of so rare an occurrence, that in the various authors I have consulted on the subject, I find only two cases mentioned. The first is a case that was admitted into Guy's hospital, in the year 1802; and the other was reported to Sir A. Cooper by Mr. Toogood, of Bridgewater, and happened in 1806: but I find very little said upon the subject. Both the above cases are mentioned by Sir Astley Cooper in his valuable work on Dislocations, p. 150 and 155. With respect to the dislocation of the hip, I shall say nothing, except that it shews how little is requisite

to be done in such cases, more than perfect rest; for, from the day of the accident, the patient never complained of pain, and said, if it was not for his knee, he felt so strong that he should be able to follow his work. I shall make no remarks upon the reduction and after-treatment, both being so fully explained in the case. The next thing that occurs to me, is, what was the cause, in this case, of the obliteration of the artery? was it from rupture of its internal coat at the time of the accident, or from subsequent inflammation about the part. In my opinion, but I may be wrong, it must have proceeded from rupture at the time of the accident, or from the artery being over-stretched and pressed upon by the condyles of the femur, during the time the dislocation was un-reduced, for I think the inflammation was not of so violent a nature as to cause obliteration, especially of so large an artery, and for so great an extent. I am also of opinion, that some of the fibrils of the nerve were ruptured, from the great pain and sensation of heat in the foot, which he experienced the whole of the time, from the accident to the time the limb was removed. The mortification, I think, is easily accounted for; for, owing to the very rigid antiphlogistic treatment adopted, acting upon his scrofulous habit, nature had not the power sufficiently to dilate the anastomosing vessels, in order to carry on the circulation in the limb.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue a abréger."—D'ALEMBERT.

Cyclopædia of Anatomy and Physiology. Edited by R. B. TODD, M.D. Lecturer on Anatomy, &c. Part VI.

IT gives us much pleasure to observe the steady progress of this valuable work. The numbers already published are a sufficient proof of the pains taken by the editor, as well as a guarantee for their continued excellence. We confess we had our doubts on its first announcement, and even for some time after the appearance of some of its earlier numbers, whether we should be justified in recommending, without further assurance of its mark and likelihood, a production which required so much time, and such able and varied assistance for its completion. Warned by the history and career of another similar performance, we were cautious. We are, however, now satisfied, that the Cyclopædia of Anatomy is a publication deserving of every encouragement. So far from having exhausted its attractions in the commencement, and then fallen off, leaving subscribers to regret their ill-advised patronage, prematurely bestowed, it increases, we think, in value in every succeeding number. The articles already given, on the subject of comparative anatomy, for example, are of transcendant merit; it will be sufficient to refer, in proof of this, to the article *Aves*, by Mr. Owen, that on *Annelida*, by Dr. Milne Edwards, *Arachnida*, by M. Audouin, and *Cetacea*, treated in the present number, by M. Frederic Cuvier. In physiology, also, we have *Asphyxia* ably discussed by Dr. Alison, and *Absorption* by Dr. Bostock. In the department of human anatomy, normal and abnormal, the editor is assisted by several first-rate contributors. In short, taken all in all, we believe the work is one that is not likely to be easily rivalled in this or any other country of Europe.

Our present notice is brief and general; but on future occasions we hope to enter more into particulars, and point out whatever strikes us as specially deserving of notice. We must not, however, close without bearing testimony to the very superior style of typography and illustration adopted in getting up the work. As to wood-engravings, they are given in profusion, and many of them beautifully executed.

Zeitschrift für die gesammte Medicin: herausgegeben von DIEFFENBACH, FRICKE, und OPPENHEIM. Band 1, Heft 4. Hamburg.

The present part closes the first volume of our Hamburgh contemporary. It contains, like its predecessors, which we noticed not long ago, much variety, and a careful selection from different quarters. The arrangement of the journal is excellent; and so far as it has gone, does great credit to the learned editors. We know no better periodical to recommend to our younger friends who are at once desirous of having a general

view of what is passing in the medical world, and of forming, at the same time, a familiar acquaintance with the noble language of Germany.

MEDICAL GAZETTE.

Saturday, May 14, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

POPULATION AND SUSTENANCE.

THE startling theorem that the population of the earth proceeds in a geometrical, while the means of support increase only in an arithmetical ratio, has given rise to numberless speculations among the political economists. Many benevolent persons have been alarmed beyond measure at the prospect, and some have even gone so far as to fancy, that when the earth is covered with people, mankind must needs devour one another. Some feeble attempts were made at first to disprove the general position, laid down so plausibly in mathematical form; these, however, having failed, the grand inquiry then became, what was best to be done? But the methods proposed for obviating the great calamity shew, that however inexpugnable the theorem itself might be considered, the doom which it threatened was not held to be so very inevitable. It was thought, on the one hand, that the means of sustenance might, by the ingenuity and industry of man, be largely increased; while, on the other, nothing less, it was supposed, would answer the purpose, than putting a check on the spread of population itself. A third party seems to be of opinion, that it would not be unwise to take advantage of both expedients.

With the latter class we must rank Dr. Loudon, of Leamington, who has just produced a pamphlet on the Equilibrium of Population and Sustenance*. This gentléman admits that the philosophers who advocate the *check*, have broached "certain doctrines alike disgraceful to those who have suggested them, and injurious to the interests of morality;" he accordingly only proposes "a mode by which, *if necessary*, a check both moral and healthful may be applied to population, founded simply on the laws of nature, which, in this as in all other cases, are so well adapted by Providence to promote the happiness and welfare of those beings which, in his wisdom, he has placed on this earth."

The reader is probably curious to know what is Dr. London's mode of restraining the population within limits. It is easily told. Mothers are to suckle their children for at least 15 months.

Dr. Loudon grounds this suggestion on some ingenious calculations. From statistical data, he deduces the age of 24 as the average age at which women marry; 44 he assumes as the average age for the termination of child-bearing: there are, therefore, 20 years available for getting a family. But the number of children to each marriage, according to Dr. Loudon, is 4·5, and one-half of them die before the completion of the 24th year: he consequently infers, that if by any means we could limit the children to four in each family, the population would not increase.

Now this he thinks might be done, both *morally* and *healthfully*, by extending the term of lactation. Ten months, he says, is the average period of suckling children in this country; increase it to 15, and we at once reduce the 4·5 in a family, to 4. But we had better quote the Doctor's own words.

---

* The Equilibrium of Population and Sustenance demonstrated; shewing, on physiological and statistical grounds, the means of obviating the fears of the late Mr. Malthus and his followers. By Charles Loudon, M.D., &c.

"The next inquiry which necessarily follows is, what increase of time, beyond the ten months of lactation, would be necessary to keep population in check, as it advances at present in England? The reply is very simple. Admit, in each instance, the nine months of gestation, the ten months of lactation, and one-tenth of the remaining thirty-five months as an equivalent for the present increase of population, and the period will be thirteen months and a half. To this, however, must be added, an allowance of six weeks for the chances of impregnation during the three months and the six weeks, on the supposition that, in every three instances of lactation, impregnation takes place once. Thus the entire time will be fifteen months, or in other words, *one-third longer than the present period.* This extension of lactation must necessarily increase the 4.5 years between each child, approximately to 5.; and, consequently, reduce the 4.5 children in a family to 4. It has been already seen, that one-half of our numbers die under the age of marriage for females; the result will then be, that there will remain only a representative for father, and a representative for mother, on an average, in every family in the country."

It is a good thing, no doubt, to have an expedient of this kind in our quiver, in case we should need it. But there is not much chance of such an emergency: at least, as *we* calculate, on Dr. Loudon's own principles. He thinks that if the number of children to each marriage were only 4, the population would not increase; whereas, it being 4·5 at present, there is some reason to be apprehensive. Now we can relieve him from at least some of this apprehension: for we can assure him that he adopts an average which is quite too high; and if 4 children to a marriage be calculated to alleviate every anxiety, be it known to him, that the actual number in this country very little exceeds that, it not being more than 4·1, or 416 to the 100. For this fact we can refer to the ablest practical statistician in England—we mean Mr. Rickman, who has settled the point not long since in this journal*.

A prolongation, therefore, of the period of lactation will not be necessary, even were it practicable. And it is lucky, as we think, that it is neither: for by what special management could the female population who are mothers be induced to suckle their infants longer than is customary? Though Dr. Loudon says that the average period at present is ten months, we have our doubts on that head: perhaps for those who do give suck, the average may be correctly stated; but when we consider the numerous disturbing causes to which women in civilized life are subject, and how many are precluded by their state of health and their habits in society from becoming nurses, we rather suspect that the period assigned is excessive. How much less likely, then, is it that mothers generally will be persuaded—no matter how patriotic the motive, to give their children fifteen months' suck?

Dr. Loudon argues ingeniously and learnedly in favour of the propriety of this lengthened period of lactation.

"It will scarcely be denied either, that, as nature has furnished the mother with the milk for a longer period than custom demands it, she had some good end in view for both mother and child; otherwise she would have stopped the secretion of the milk at a definite time, in like manner as she has made the period of gestation definite. The circumstance of a child being, in comparison with the young of the lower animals, so long unable to provide for itself, strongly tends to corroborate the proofs already advanced, that nature had in view a more protracted period for lactation than is now allowed. Some of the older French writers, following, as they believed, the laws of nature, fixed the period of weaning at about fifteen months; at which time they supposed the infant had got its eight incisors and four canine teeth. Desormeaux mentions in-

* MEDICAL GAZETTE, xvi. p. 654.

stances of mothers suckling children for three, four, five, and even seven consecutive years.

"That the period of lactation has a great influence over the numbers of mankind in various countries, is proved by numerous facts. In China, where the population is so great that the inhabitants adopt the inhuman practice of infanticide, 'as soon as a child can put its hand to its mouth, it is weaned, and taught the use of its right hand.' On the other hand, Hunter mentions, in the Memoirs of his Captivity amongst the Indians of North America, that whenever their children are sufficiently old and strong, the Indian mothers 'wean them, and suffer them to run about generally between the age of two and three years.' This circumstance will alone account for the thinness of these tribes in a fertile country, when compared with other barbarous and even civilized nations. Dr. Lowenfeld has remarked a similar extension of lactation amongst the Carribean tribes, to the south of Berbice, Essequibo, and Demerara. There, also, the population is remarkable for the paucity of numbers in proportion to the fertility of the soil; and what is of more importance, such a number as seven or eight to a family is scarcely known. It is highly probable, also, that a like cause exists for the decrease of the negro population in Jamaica, not only amongst the Maroons, but amongst the imported Africans, which circumstance will more satisfactorily account for the falling off of the negro population, than the alleged cruelty of the planters, brought forward a few years ago, in the House of Commons, by Mr. Fowell Buxton."

We ought, however, to add, that it is not to be inferred from the seriousness with which the author recommends his "moral and healthful check," that he has any wish to inculcate its adoption in the actual circumstances of the country; he merely intends it as a measure of reserve, in case hereafter there should be some pressure of necessity. And that this is not likely soon to occur he has no hesitation in admitting, on the authority of some late eminent writers, who hold that the resources of mankind for the production of food, in the Western world alone, are such as to meet every possible increase of population for an indefinite number of ages to come.

FACTORIES' REGULATION BILL.

A NEW bill, of a very questionable, or rather an unquestionably bad, character, was read a second time in the House of Commons on Monday evening; the amendment for postponing it to "that day six months" being negatived by a majority of only 2, where 354 voted. Our readers will recollect that, by the act of 1833, it was so ordered that after thirty calendar months, children under 13 years of age were to be protected from more than *eight* hours' labour. Those thirty months expired on the 1st of March last; and the new provision has no sooner come into operation, after two years and a half of anxious expectation, than another measure is introduced, whereby children of 12 and upwards are to be worked for *twelve* hours daily, or *sixty-nine* hours a week. Mr. Poulett Thomson moved the second reading; the amendment was moved in an able speech by Lord Ashley. "He had supported the original bill," his Lordship said, "and he would oppose the present one on *medical* grounds chiefly. He found from the report of the commissioners, that out of thirty-one medical gentlemen who had been examined, no less than sixteen were opposed to the present bill, and in favour of a ten hours' bill, stating that the latter was the full amount of labour to which children ought to be subjected. Of the remaining fifteen gentlemen, Dr. Shaw, of Manchester, said that from ten to eleven hours were sufficient. Mr. Roberton and Dr. Bardsley said much the same. Dr. Carbutt, of Manchester, seemed uncertain, and said, perhaps twelve hours; but of all the fif-

teen, there was only one medical man (Dr. Phillips, of Manchester) who boldly asserted that twelve hours' labour was by no means injurious. All these witnesses were speaking as to the employment of persons under and up to 18 years of age. The evidence of the report shewed, that the excessive fatigue of twelve hours' labour, the want of sleep, the peculiar attitude in which the labour was performed, the heat of the atmosphere in which the work was done, tended to, and frequently terminated in, permanent disease; and the Commissioners themselves, in their report, proposed that until the commencement of 14 years of age, the hours of labour should not exceed eight hours a day." Yet in the teeth of all this evidence, the infant operatives are to be worked twelve hours a day, to satisfy the cupidity of certain master manufacturers, who have influence with men in power!

The debate on Monday night possessed much interest. Mr. Brotherton, the member for Salford, made a very excellent speech, tracing the whole history of legislation in this country, on the subject of labour in the factories, for the last thirty years. But useless was all reasoning from medical or other experience: the ministerial party had it their own way. Let us hope, however, that in Committee, or in passing the House of Lords, the measure may still be so modified as not to fix a permanent stain upon the character of England, by offending so outrageously against both humanity and justice.

MR. WARBURTON AND THE DEPUTATION TO THE CHANCELLOR OF THE EXCHEQUER.

It appears from a paragraph in the Court Circular, that certain Licentiates of the College of Physicians, headed by Mr. Warburton, have had an interview with the Chancellor of the Exchequer. — But *no meeting of the Licentiates has been convened*, although we are informed that several convocations have taken place of some eight or ten physicians who happen to be Licentiates. The fact is, that on the Petition of the Licentiates being presented to parliament two or three years ago, an attempt was made to form an Association, but the great body of the Licentiates declined to have any thing to do with it. May we inquire whether the gentlemen who recently waited on Mr. Spring Rice had the candour to explain this to him, and that they could only give their opinions in their individual capacity? Again: Mr. Warburton, as chairman of the medical committee, has voluntarily placed himself in a situation in which impartiality is looked upon as a cardinal virtue—not less necessary than uprightness in a judge. How does he reconcile this with the fact of heading a deputation composed of gentlemen avowedly and actively at variance with their College? We shall recur to these questions hereafter—meantime "we pause for a reply!"

TRIBUTE TO SIR CHARLES BELL.

We understand that some of the friends and pupils of Sir Charles Bell intend to present him with a tribute of their respect and regard on his leaving London for the northern metropolis. The subscription from each is limited to a guinea, and its object being to obtain many names rather than a large amount, we have satisfaction in stating that more than a hundred gentlemen have already enrolled themselves in the list.

MEDICAL INSTITUTIONS OF IRELAND.

In another part of our present number will be found the first portion of a report on the medical establishments of the sister island; a valuable and curious document, drawn up with great ability, by Dr. Borrett, one of the assistant commissioners appointed by government. We shall take another opportunity of noticing its details.

M. BROUSSAIS AND HIS PHRENOLOGICAL LECTURES.

After some years of repose and comparative oblivion, the veteran *physiolo-*

gist (as he was once called *par excellence*, by his disciples) has taken the field in a new warfare. We fear he has forgotten the sage maxim,

> "Solve senescentem mature sanus equum;"

but let us hear what our able contemporary, the *Gazette Médicale*, says of him. A more skilful dissection of the character and pretensions of M. Broussais we have not hitherto met with:—

M. Broussais setting up for professor of phrenology! What a falling off is there, for a man who could once boast of being at the head of an imposing school! We should think he had better remained in peace, brooding over the pleasant recollections of his ancient triumphs, than have entered on a new career, for which his education, literary and scientific, and the peculiar character of his mind, render him so totally unfit. He gives up medicine, and plays the philosopher. Philosophy, no doubt, is an excellent thing to put in practice: it has been, from the earliest times, the great resource for fallen greatness, glory obscured, and ambition blighted. M. Broussais might find it serviceable in this respect; for having closed his mission long ago, he had nothing now to do but to enjoy his retreat peaceably, cultivating his garden, and receiving the occasional visits of some of his old friends. But this is not the sort of philosophy for M. Broussais. He is not one of those who hastily abdicate; after struggling as long as possible against the torrent which utterly swept away his medical doctrines, he did not quit the field till perfectly assured that all his ideas lay dead upon the plain, and that he had not a single soldier left. It is after all this that he has determined to open another campaign, in a new seat of war, against new enemies, and with another army.

But the enterprise is evidently beyond his powers. The two lectures hitherto delivered have shown the public what *we* were quite prepared for—that though M. Broussais may have a taste or a passion for philosophy, he is wholly incapable of philosophising. His mind, whether owing to some innate defect or want of early culture in that direction, is obstinately adverse to it. He neither thoroughly understands the questions he treats of, the systems which he combats or supports, nor the very language he uses. Completely out of his latitude, he feels that he cannot proceed safely without sounding at every inch of his progress; he does not know what shoals and quicksands beset him: he is not even acquainted with the narratives of preceding voyagers; and his perils in the deep are only so much the more frequent and the more dangerous as he advances with intrepidity and a most hazardous assurance. M. Broussais fancies himself a metaphysician, a psychologist, a moralist, a philosopher in short, simply because he is acquainted with medicine, for medicine comprehends physiology, a science which, according to him, is the science of man. He thinks it is enough to substitute for the terms, ideology, psychology, or metaphysics, that of the *physiology of the brain*, in order to solve all problems, all questions coming under these denominations, and that in this way he may mount up to Plato, Descartes, Leibnitz, Locke, Kant, and all the other sages that ever lived,—for it is beyond a doubt that people cannot think without a head. And, accordingly, it is marvellous to witness with what superiority he treats those poor philosophers who venture to talk of the human mind, without being acquainted with the brain.

We have never thought phrenology worthy of a serious discussion: as a psychological system, it is contradictory in its very conception; as an anatomico-physiological theory, it is an hypothesis wholly destitute of proofs. It is a theme for the day, on which some varnish of science and philosophy may be thrown, but which, for those who think deeply or seriously, is destitute of any really scientific character. Charlatans have got hold of it, and make a trade of it, just as the nativity-casters of old made a trade of astrology. Among its supporters, always excepting M. Broussais, there is not an individual whose name possesses the least weight. It is deserving of remark, that not one of the eminent zoologists and comparative anatomists of the age, who have so deeply studied the organization of living beings and the higher physiology, have even deemed it worthy of notice. Cuvier never spoke of it without disdain. MM. de Blainville, Geoffroy St. Hilaire, Serres, Flourens, Magendie, Dumeril, Dutrochet, and all those physiologists whose names have become famous throughout Europe, never thought it deserving of

attention. The same thing is true with respect to England:—with the exception of Mr. G. Combe, a man of talent and cleverness, who has become the official champion of phrenology in that country, as M. Broussais has in France, nobody of any note has taken it up. In Germany, the cradle of organology, this pretended science exists only as a name. All the great anatomists and physiologists, the Rudolphis, the Treviranus', the Meckels, the Carus', the Tiedemanns, &c. whose doctrines mark the highest and most advanced state of science at the present æra, say nothing about it. Everywhere, in short, throughout Europe, what is called phrenology is thrown aside into the by-places of science and the learned world: the study of it is everywhere left to the trading trickery of charlatanism.

Now, M. Broussais' phrenology is in no way different from that which is met with elsewhere; it is not a whit more profound, more learned, or more ingenious: it is an insipid reproduction of all that Gall and Spurzheim, and their followers, have repeated *ad nauseam.* The course, therefore, if we may judge by the two lectures already delivered, will offer nothing original in its matter, while its manner, excepting, perhaps, some sallies of controversial irritability indulged in by the professor, and which may be thought amusing, is, in every other respect, of the most vulgar and common place kind. Whenever M. Broussais quits the tangible arena of anatomy, and attempts to soar in the region of metaphysics, his language becomes almost unintelligible, because he does not altogether understand it himself, nor is he perfectly acquainted with the words which he employs. It is but too evident, that these abstract researches are beyond the ordinary range of his powers. The phenomena of mind, rational and moral, escape him on all sides through their subtlety and complexity; he can neither analyse, observe, or describe them. In vain would he persuade his hearers that all is capable of being reduced to sensible facts, and that physiology embraces every thing; he is obliged to borrow the language of the psychologists, for his physiology fails him. The words liberty, morality, inclination, instinct, passion, sentiment, faculties, intelligence, will, desire, attention, conscience, judgment, reason, idea, exist in all languages, for the things which they represent exist in the human mind, and those things constitute the material of the moral science which M. Broussais calls phrenology. Moral science, however, is very intricate; it is not to be learned in camps or in hospitals; it presupposes literary studies. Now M. Broussais has never had the opportunity of philosophising to any purpose. Not that his mind is not of an abundantly speculative cast, for all his works show the contrary: but this tendency, though it were to amount to a monomania, would not still be a whit the more philosophical. He has some resemblance to those poets,—

"Qui prennent pour génie une ardeur de rimer."

He throws himself recklessly among those problems which have exercised the sagacity of the greatest minds,—about the data he cares not; nor does he spend a thought in inquiring whether any one ever entertained those questions before him. It is marvellous to observe him cutting and slashing, dogmatising and concluding, in matters about which he knows just as much as he does about hydrostatics.

We shall not attempt to enter into a critical detail of M. Broussais' lectures. A volume would not suffice for pointing out all their errors, contradictions, and anomalies of every sort. Some journals have promised analyses, which we think they will not easily perform, unless they can first translate the lectures into intelligible language. Either report or analysis *we* deem unnecessary. Most of our readers are acquainted long since with the *philosophy of irritation*, and, as to the phrenology, for a franc M. Hottin's synoptical table may be purchased, which will tell all that the professor knows or can teach on the subject. We may notice, however, a few points cursorily.

"What is phrenology?" says M. Broussais, in his opening lecture. M. Lelut, in an excellent book published a few days ago, has considered phrenology as a system of psychology: but M. Broussais rejects the definition with a kind of horror; in his opinion the word psychology should never be pronounced within the walls of a school of medicine. Phrenology, says he, is not a psychology, it is *the physiology of the brain.* Every one, of course, may choose his own definitions, nor shall we quarrel with that now

given: but we must take leave to say, that M. Lelut seems to be a better Grecian and etymologist than M. Broussais, for the terms *phrenology* and *psychology* are as nearly as possible synonymous, implying doctrines respecting the mind or the soul. The very name of the pretended science is a contradiction—a misnomer: craniology, organology, better express what it is said to mean. Did we think it worth while to propose a more fitting appellation, we should suggest *encephalology*, as limiting formally to the study of the *brain* a science with which the *mind* has so little to do.

Having thus defined phrenology to his satisfaction, M. Broussais plunges at once into the darkness of metaphysics. Forsaking wholly his four busts in plaster and pasteboard, he sets himself to talk of Plato, Aristotle, Descartes, Kant, Locke, Reid, and Condillac, passing before him in review all ancient and modern philosophy. In the course of his lectures he may say many wonderful things, but it is quite impossible he can surpass this extraordinary digression on philosophy. Only imagine a man, of talent and ingenuity if you please, but without any previous study, undertaking to lecture on astronomy!—applying the technical terms of that science at random — parallax, aberration, nutation, right ascension, precession, apsides, syzygies, &c. — quoting Eratosthenes, Hipparchus, Ptolemy, Tycho-Brahe, Kepler, Copernicus, and criticizing Newton, Laplace, and Herschel, without ever having read or understood their writings. So in a great degree was it with M. Broussais, in his critical expositions of the philosophers of mind.

But what was perhaps most worthy of admiration, next to the assurance of the Professor, was the simple docile good faith of his audience. Who could have thought, that in the country of Descartes, such teaching would be listened to with acceptation and applause? The authority, the celebrity, and the popularity of the Professor, no doubt contributed much to this result. But the bulk of the audience consisted of the students of the school, who know no more of phrenology than they can see in M. Guy's shop, and who have no further tincture of philosophy than the few words gathered for their bachelor's degree. Of such auditors, phrenology, professing to rest on anatomical and physiological data, is a philosophy altogether to the taste: they are delighted to hear from the lips of M. Broussais that intellectual and moral science is nothing more than the physical science of man; and that, in order to understand the human mind, it is only necessary to study the brain. All this, however, is great nonsense: change of words cannot alter things; and, deceive himself as he may, the professor cannot advance a step in his subject without leaving his physiology behind him, and getting into the province of psychology. Curious as it may seem, M. Broussais appears to have been so much the dupe of his own phraseology as to have actually taught for three hours a science the very name of which he would not pronounce in a medical amphitheatre, lest the walls should tumble upon him!

In his second lecture, M. Broussais entered into a long exposition of the gradual development of the intellect of the fœtus, of the infant, of the adult, in man, and other animals. He only repeated, in the trite, commonplace way, what is to be met with every where since Buffon's time, in all treatises and manuals of physiology and natural history. As usual, he often mistook hypotheses for facts. He also set up a classification of the faculties of his own, in opposition to those of several philosophers — particularly those of the eighteenth century. In these digressions, so thick was the obscurity at times that nothing whatever could be seen. Reid, Descartes, Berkeley, &c. were occasionally brought on the scene, or at least certain shreds and patches of their doctrines, which were compared, confounded, distorted, and mutilated, in the most cruel manner. We shall be heartily glad when M. Broussais comes to phrenology in earnest—that is to say, to the enumeration of the 27 organs of Gall, or the 35 of Spurzheim, whichever he pleases, so well mapped out in plaster by M. Dumontier, but so invisible in nature: he will be here much more at home than in those metaphysical regions where, at present, he scrambles so much in the dark. Let him speak of the brain, its convolutions, its commissures, its divergent and convergent fibres, for this is of the province of anatomy and physiology; but let him, once for all, allow to rest in peace Plato and his *ideas*, Aristotle and his logic, Descartes and

his *cogito*, together with the Germans, the English, and the Scotch, for they are certainly wholly out of his province.

We do not intend to trouble our readers with further notice of M. Broussais' course; it would be only trespassing on their patience.

Since the preceding was written, the course of phrenology has been discontinued, for what reason we do not exactly know.

ROYAL INSTITUTION.

Friday, April 29, 1836.

Professor Faraday on Plumbago.

A VERY large audience was assembled to hear the lecture this evening. Dr. Faraday began by noticing the ordinary uses of plumbago, or black lead, as familiarly employed in the arts for the purposes of writing and drawing. He considered it as one of the many forms which carbon assumes in nature, but which it was totally out of our power artificially to produce. Charcoal, as manufactured in certain processes, exhibited sometimes a layer of plumbago on its surface, distinguished by its glistening aspect, but so thin as to be totally useless. Iron also is sometimes converted into a kind of plumbago, by the action of dilute muriatic acid, or even sea-water: as, for example, the iron used for protecting the copper bottoms of ships, on Sir H. Davy's plan. Plumbago is also generated in small quantity during the preparation of cast iron.

Several of the properties of plumbago were then described—such as its remarkable power of resisting heat, which renders it so excellent a substance for the manufacture of crucibles and furnaces. The feebly conducting power of plumbago, with regard to heat, was beautifully and simply exhibited by the friction of a metal button; when rubbed strongly, five or six times, on a bare board, it ignited phosphorus on being applied to it; but coat the board with plumbago, and then rub the button, it will be found that double the quantity of friction will scarcely produce the same effect.

A great desideratum is the power of hardening ordinary plumbago to any required extent: we can soften it at pleasure, but to give it only one degree of hardness—to be able to alter its consistency, for example, from that of H to HH as sold in the shops—would be so desirable to the manufacturer that he could afford a large premium for the discovery. Mr. Mordan would give 1000*l*. to be in possession of such a power. The plumbago, procured in nature, is of very different degrees of value; and that used for black lead pencils varies in price from 30*s*. the cwt. to 30*s*. or even 45*s*. the lb. The best comes from Borrowdale, in Cumberland, is brought to a single depôt in London, whence it is issued to every part of the British empire. Dr. Faraday's account of the plumbago market was amusing: it is held, on the first Monday of every month, at a public house in Essex Street, Strand, where agents from all the manufacturers who use black lead meet together. The same lumps of plumbago are frequently presented month after month for sale; but when any new pieces are produced the greatest excitement prevails—their quality is closely examined, and the purchasers who have the first choice are obliged to pay as much as 45*s*. a lb. for their sample. But few manufacturers went to this expense: the great majority were content with the inferior kinds; and even the very dust of plumbago was turned to account in making pencils "for sale." The dust was mixed with the sulphuret of antimony and made into a paste, which was then spun out like vermicelli, to be embedded in wooden handles, and sold at the stalls and by hawkers for a few pence per dozen. But the practice of the best pencil makers was very different: none but the most expensive plumbago was suited to their purposes; and, notwithstanding the perfection to which the machinery for manufacturing pencils was brought, such was the waste of the valuable material that no more than half an ounce of "leads" for ever-pointed pencils could be procured from a pound of pure plumbago. It may be laid down as a fact, that a good cedar pencil cannot be sold for less than sixpence, nor a dozen points for less than half-a-crown. The latter part of this interesting lecture was devoted to a description of Mr. Mordan's machinery for pencil making, which, by the favour of Mr. Mordan, was submitted to the inspection of the audience, and actually worked before them. All the processes were performed by three experienced workmen who were in attendance.

Friday, May 6, 1836.

Professor Daniel on a new and constant Galvanic Arrangement.

In a paper recently read before the Royal Society, Mr. Daniel has given an account of a new galvanic circuit, having striking and valuable properties. He gave a familiar explanation of it this evening to the members of the Royal In-

stitution. After a just tribute to Dr. Faraday, to whom he acknowledged himself indebted for the fundamental idea of his new plan, he proceeded to lay down certain principles relative to the mutual action of the metals and fluids employed in the voltaic circuit. He found, he said, that the ordinary battery soon became exhausted, by the platina, or copper, becoming coated with zinc; and this suggested to him one part of his present contrivance —namely, the enclosing the zinc in animal membrane. Another point on which he expressed himself satisfied, was, that the extent of surface of the zinc was immaterial: a small stick of zinc was sufficient to oppose to a large plate of copper, silver, or platina. Hence he was led to the construction of a simple but very effective battery. He took a cylindrical copper can, about eight or nine inches in height and three in diameter, within which, enclosed in a tube of animal membrane, he suspended a slender stick of zinc. The tube was fixed to the bottom, which was perforated, the aperture being connected with a glass syphon passing from the bottom of the can to its side, along which it ascended to an equal height. Dilute sulphuric acid was then introduced into the membranous tube, and solution of sulphate of copper into the space around it. The arrangement was then ready for action, and the circuit was formed by connecting the zinc with the copper, little cups containing mercury being attached to each. A set of eight or ten of these cans, or cylinders, when put in action, produced a brilliant intense spark, and ignited iron wire. Oxygen and hydrogen gases might be readily procured by introducing the positive and negative wires into separate glass jars in a water-trough; and as the action of the battery could be kept up for hours, or at pleasure, Mr. Daniel thought that it would afford the readiest source for procuring those gases pure, for experimental or for laboratory purposes. The whole arrangement was exhibited in action, and seemed to act admirably. The only attention required during the operation of the battery, was to renew occasionally the dilute acid and the solution of the copper salt. The former was done by simply pouring in fresh acid, the fluid already within the membrane being carried off by the syphon: the sulphate of copper was supplied by allowing that substance to drop into the exhausted solution from a colander-like dish, fitting between the membranous tube and the sides of the can. If this arrangement can be made to work on a large scale as effectually as it does in the lecture-room, and as economically as it promises, it must prove a highly valuable acquisition to the practical chemist.

ON DISEASES OF THE SPLEEN,

AS THEY OCCUR IN INDIA.

By J. O. Voigt,
Physician to the Danish Establishment of Frederiksnagor (Serampore).

Chronic diseases of the spleen are so frequent and fatal throughout India, especially in the low marshy provinces of Bengal, that we have good reason to complain of the neglect with which they have hitherto been treated. Most writers on the diseases of warm climates either content themselves with merely mentioning them, or else despatch them in just as unsatisfactory a manner as the authors of general systems of medicine. Even Dr. James Johnson, in his excellent work on Tropical Climates, passes them over altogether; and Annesley's voluminous "*Researches*" and "*Sketches*" contain comparatively little on the subject. Mr. Twining, however, surgeon to the general hospital in Calcutta, has given, in the third volume of the Transactions of the Medical Society of that city, a good treatise on Splenalgia.

The chief forms under which Dr. Voigt observed affections of the spleen to occur were, what he terms *splenitis chronica*, *splenalgia congestionis*, and *lien ingens*.

Chronic splenitis displays a more or less clearly marked inflammatory diathesis, and is attended with pyrexia, considerable pain, and an uncommon degree of weakness: it chiefly attacks children of European origin, and those of rich natives, as well as persons of a more advanced age who are addicted to a stimulating diet; and appears to be principally seated in the proper membrane of the spleen. The swelling, in the first stage, is never very great, and often scarcely perceptible.

Congestion of the spleen (or splenemphraxis) shews plain marks of an atonic diathesis, and is not at all, or but to a trifling extent, attended with febrile symptoms; it does not occasion much pain, but causes a considerable tumor, which occasionally fills the whole of the epigastric and mesogastric regions. This disease most generally occurs among the natives, and is seated in the spongy parenchyma of the organ.

Enlargement of the spleen often occurs and continues for a considerable period without pain or injury to the constitution; it does not appear to be attended with any obstruction, and is observed mostly amongst elderly individuals of the natives.

1. *Chronic splenitis* generally commences with anorexia, restlessness, sleeplessness, and a peculiar irritability of mind, which

is especially remarkable in children. They gradually lose all desire for play, wish to be constantly carried, hang the head, cry frequently, and manifest the greatest indifference to all that passes around them. After these precursory symptoms have continued for some days, and sometimes even two or three weeks, the essential symptoms of the disease begin gradually to appear. The face becomes pale, lead-coloured, or sallow, and the conjunctiva of a pale bluish colour. The skin, especially of the abdomen, communicates a disagreeable sensation of heat and dryness, and the patient falls into a state of weakness greatly disproportionate to the duration and degree of the attack. The pulse is frequent and somewhat hard, and headache, a peculiar uneasiness, slight difficulty of respiration, palpitations, and occasionally pain in the left shoulder, supervene. There is a constant feeling of tenderness and weight in the left hypochondrium, which is increased by pressure, and that often so much as to cause a loud scream. On examining the patient while lying on his back, and pressing with the fingers under the false ribs of the left side, a hard tumor is felt, which is greater or less according to circumstances, but is always of much smaller dimensions than in cases of splenalgia congestionis. The erect posture is uncomfortable to him: he likes best to lie on his left side, with the body somewhat curved. Although the tongue is moist and clean, he complains of thirst, and, after his meals, of gastrodynia, flatulence, and *ardor ventriculi*. The bowels are very irregular, but generally costive; the fæces are brown, green, or sometimes black; and the urine is pale and copious. After an uncertain period, the disease terminates either by recovery, or by passing into other diseases, and causing death.

2. *Splenalgia congestionis* is the most usual of the chronic spleen diseases prevalent about Serampore. Its most remarkable precursory symptoms are lassitude, heaviness, a dislike to any kind of exertion, weakness, costiveness, and a sense of heat in the left hypochondrium. These are followed, after some time, by a tumor in the region of the spleen, which, though tender to the touch, is by no means so much so as in chronic splenitis. On the other hand, its bulk increases to such a degree that it generally occupies the entire of the left hypochondrium, and of the epigastrium strictly so called, and sometimes of the epigastric and mesogastric regions. The skin is dry and cold, and the cutaneous veins of the abdominal region are considerably dilated, and present a reticulated appearance. The patient experiences an indescribable lassitude and weakness, together with vertigo; the lips and gums lose their colour; and the face becomes dingy, sallow, and cachectic. The bowels are tardy and constipated; the fæces dark coloured; the urine pale and copious; the pulse small and feeble; the tongue generally clean and moist, and the appetite good and sometimes even voracious; but the process of assimilation goes on very imperfectly. In proportion as the strength diminishes, the flatulence, anxiety, and irritability increase; the extremities are reduced to skin and bone; cough and dyspnœa set in, and the feet become œdematous. The pulse is sometimes quickened towards evening, and the patient then suffers from an insupportable inward heat, which prevents sleep. He cannot bear to lie upon his right side, and sometimes not even on his back, but finds lying on his left side, with the body curved, the least uneasy posture. When walking, he generally bends to the left, and supports the left hypochondrium with his hand. The disease in females is generally attended with amenorrhœa. These symptoms, which, with a few exceptions, appear in every case of simple congestion of the spleen, continue till the disease is removed, or terminates in others, and eventually in death.

3. *Enlargement of the spleen* is generally observed amongst elderly natives, and is undoubtedly, in most cases, a sequela of mild intermittent fevers. The tumor is soft, not of very great magnitude, bears pressure, and produces no inconvenience except a sensation of weight. It does not appear probable that there can be any obstruction existing in such cases, which probably are of the same nature as those mentioned by Regia (Specim. observat. anat. and pathol. Ticin. 1784), in which, according to that author, the vessels can be beautifully injected.

The cachexia connected with *splenalgia Bengalensis* frequently manifests itself by a malignant ulceration, the disposition to which is so great, that leech-bites and blisters occasionally give rise to foul or phagedenic ulcers, which, in cases where mercury has been employed, and the patient is in a swampy situation, and debarred from free access of air, occasionally terminate fatally. *Stomacace* also, both simple and scorbutic, often occurs among the poorer natives; and although most authors recommend mercury in splenalgia, it is an indisputable fact that even a very small quantity (a few grains, for instance) generally occasions a profuse salivation, and occasionally so violent a *stomacace mercurialis*, that mortification sets in, the teeth drop out, the bones become carious, and death ensues.

We have given the description of the symptoms thus at length, as well because it is the most circumstantial that we have met with, as that it may have the effect of inducing the profession in those countries to pay more attention to diseases of the spleen than they have hitherto done. From contemplating a disease in its most exquisite form, as existing where circumstances are most favourable to its development, we are the better able to judge of its pathology, and of its bearings in various respects; and it is not unlikely that, even in this country, many symptoms, generally attributed to dyspepsia, &c. may arise from a milder form of the chronic splenitis above described. We learn, too, that this disease may exist to a considerable extent without producing any very perceptible tumor; and, on the whole, it is not unreasonable to conclude that a chronic morbid action, sufficient to produce considerable uneasiness and constitutional disturbance, may be going on in the spleen, for some time, without giving rise to any symptoms of such a nature as to lead us to suspect its seat to be in the organ.

As the author, on account of the prejudices of both natives and Europeans, has not had the opportunities that English medical men attached to the army or to hospitals in India have enjoyed, he is obliged to refer to them for a description of the appearances observed in the spleen after death. Proceeding next to the etiology of the disease, he contradicts Annesley's assertion respecting its comparative infrequency in India, and states that, at least in Bengal, the case is quite the reverse, both according to his own experience and that of Mr. Twining. The predisposing causes he mentions are:—1, season; splenalgia, though occurring at all times of the year, being most prevalent towards the conclusion of the periodic rain, and at the commencement of the cold season: 2, age and sex; children and delicate young men being most subject to it, while elderly persons, and women after puberty, are comparatively exempt: 3, low swampy situations, overgrown with jungle: 4, perhaps sol-lunar influence.

The most usual occasional causes are: 1, tedious remittent and intermittent fevers: 2, want of exercise and of proper clothing, unwholesome diet, and intemperance in eating; these causes often produce an idiopathic splenalgia among the natives: 3, abuse of stimulants, especially arrack: 4, opium-eating: 5, everything that has a tendency to debilitate the system in general, and the digestive system in particular; such, for instance, as depressing passions, &c.: 6, external injuries, such as contusions from falls; but this cause does not often come into play.

In speaking of the proximate cause of splenalgia, there is a remarkable coincidence in opinion between the author and Dr. Hodgkin, in his Essay on the Uses of the Spleen. After stating that it has been proved by the experiments of Defermon on animals, that the spleen is capable of admitting a considerable variation in its size, and that its vessels can bear to be greatly dilated for some time, without producing any local or general obstruction, he proceeds to observe that it is evident that, under particular circumstances, in the cold stage of intermittent fever, for instance, there is a large quantity of blood thrown in upon the abdominal viscera, which would have a most destructive effect upon the more important organs, if the spleen, from its spongy and elastic texture, were not adapted to serve as a temporary reservoir for a considerable portion of the superabundant fluid; and that repeated and prolonged congestions of this description must, in persons who have been exposed to miasmata and other debilitating causes, produce a state of irritation of the organ, which may terminate in chronic inflammation, or in an incurable induration.

Treatment.—The disease is always difficult to cure, mostly very obstinate, and frequently fatal. Accordingly Dr. V. describes, at a length commensurate with the difficulty and importance of the subject, the treatment that has been found most successful in its different forms; and makes some useful practical remarks on the inconveniences attending other modes that have been proposed by different individuals: the use of mercury, for instance, he most strongly reprobates. The measures he recommends, besides attention to the diet, &c., are to attack the inflammatory symptoms, when such are present, by leeches, gentle purgatives, tepid baths, and the application to the region of the spleen of a cloth dipped in nitro muriatic acid considerably diluted with water, and covered with an emollient cataplasm; both to be frequently changed.

The febrile irritation and local inflammation once removed, the next indication is to endeavour to diminish the bulk of the spleen. This is most likely to be effected by the continued use of purgatives combined with tonics, and by certain topical applications. He considers the preparations of iron in general, and the sulphate more especially, to have some specific influence on the spleen; but advises caution in its application, as an overdose readily produces cardialgia, gastrodynia, vomiting, and diarrhœa; and it is absolutely contra-

indicated where there is any febrile irritation present, as well as in hepatic, pleuritic, and dysenteric complications. The other internal remedies are aloes and myrrh, combined with senna, gentian, carminatives, diuretics, and diaphoretics; nitric acid; and tartar emetic in small doses. The topical applications are, friction with the flesh-brush, nitro-muriatic epithems, small blisters, stimulating liniments to the abdomen, and moxas.

The treatment of chronic splenitis, or of congestion of the spleen, difficult enough when they are simple, is rendered still more so by their complication with other diseases; for instance, in *splenalgia hepatica*, mercury, though indicated for the liver, cannot be employed, as it increases the spleen disease.

In another part of the paper Dr. Voigt makes the following remarks on the terminations of splenalgia. "In Bengal, it rarely runs on to suppuration, but, when not fatal, it generally terminates in induration, if not cured in time. The febrile symptoms then disappear, and the pain in the left hypochondrium is much diminished, but the tumor remains, and becomes hard and distinct. The health improves, and, with the exception of costiveness, a sensation of fulness and weight under the left false ribs, a dry cough, some dyspnœa, and occasionally a slight pain shooting to the scapula, the patient feels pretty well, and may live on for many years in that condition. He is, however, generally predisposed by it to fever, liver complaints, dysentery, dropsy, and cholera, by some one or other of which he is at last carried off. Splenalgia, especially when complicated, sometimes runs its course very rapidly, and may terminate in death in three weeks or a month. Œdema of the feet and legs, ascites, dysentery, ecchymoses, a malignant stomacace, and singultus, are the general precursors of death in subacute cases, whilst obstinate diarrhœa and hectic close the scene in the most usual form, splenalgia congestionis. Persons who have once had chronic disease of the spleen, are very liable to be attacked by it again.—*British and Foreign Medical Review, from Bibliothek for Læger*, No. 2, 1834. Copenhagen.

NEW MODE OF TREATING

LUXATIONS OF THE STERNAL END OF THE CLAVICLE.

By M. Velpeau.

No luxation is more easily reduced, or with more difficulty retained in its place. The difficulty is owing to the endeavour of the surgeon to oppose the power which tends to carry the clavicle forwards, instead of relaxing the muscles whose action oppose his wishes. Anatomy and experience shew that in these cases the anterior sterno-clavicular and inter-clavicular ligaments are broken, and that dislocation necessarily follows, as the articular surfaces are so constructed that they do not offer any resistance to the muscles, which immediately displace the end of the bone: the pectoralis major and internal portion of the deltoid drawing it forward, the trapezius and sterno-cleido-mastoideus drawing it upwards; whilst both sets are assisted by the large muscles of the trunk attached to the scapulæ. The deltoid, pectoralis major, sterno-cleido-mastoideus, and trapezius, are relaxed, and the rest neutralized, by carrying the elbow inwards and forwards to the lower part of the sternum, so that the hand may rest upon the opposite shoulder: when this is done, the bone returns to its place. It can be retained there by the following apparatus: a towel, folded thrice, is first placed round the thorax, and retained by braces attached to its upper border. The arm is then placed in the necessary position, and held by an assistant. The surgeon fixes the end of a bandage (eight yards in length) under the armpit of the sound side; brings it behind over the luxated clavicle; then downwards over a part of the arm; passes it behind and beneath the elbow; then again under the sound armpit, behind the chest, above and before the injured clavicle, so as to make three or four turns like the first. Next he passes the bandage, which has just embraced the elbow, over the fore-arm, then on the sound clavicle, between the hand and the neck, instead of passing it under the armpit as before; after which he passes it downwards behind the thorax, towards the elbow, bringing it again on the fore arm and clavicle, and making thus three or four diagonal turns. After this the bandage is not again passed under the elbow, but it is passed two or three times from below upwards round the chest and the bent arm: the remaining part is expended by making a few turns like the first, fixed by two or three circular ones. The whole is fixed by pins, and secured by a napkin covering all. This bandage may remain a month or more without any displacement. A more simple contrivance is a belt, or band, passing round the body, and having in front a deep pouch for the elbow. When the belt is fixed, and the elbow placed in the pouch, the belt must be drawn forcibly upwards towards the clavicles, and fixed there by braces over

the shoulders, which are attached to the upper border of the pouch, as well as to the edges of the body belt.—*British and Foreign Med. Rev., from the Journ. Hebdom. de Méd.*, May 30, 1835.

DISEASES OF SILK-WORMS.

M. Bassi, in his work on this subject, gives an account of a malady called the *muscardine*, to which the silk-worm is subject. It is the result of the growth of a vegetable substance (a moss, the *Botrytis bassiana*), the germ of which enters the body of the worm, kills it, and then appears on the surface in the shape of a whitish efflorescence. This disease, according to M Bassi, is not epidemic, but contagious; for it is communicable, by contact and inoculation, to other silk-worms and different kinds of moths. The knowledge of the cause and effects of the malady has led the author to a rational mode of treatment.—*Gaz. Medicale.*

TINCTURE OF COPAIBA.

A correspondent describes the following as "the least nauseous, and most available form for administering the balsam of copaiba:—Take twelve ounces of copaiba, and six of calcined magnesia, rub together, and then digest in a pint of proof spirit; filter, and add half an ounce of the spirit of nitrous ether. Of this a drachm two or three times a day, gradually increased to half an ounce at a time, will prove a sufficient dose. The tincture, when first made, is transparent and colourless, but assumes an orange tint on keeping."

THE LATE MR. MILLARD.

(From a Correspondent.)

It is with much regret we announce the decease of Mr. Millard, the late Demonstrator of Anatomy at the Webb-Street School, who died of phthisis at his house in Abingdon-Street, on Saturday the 7th instant, in the twenty seventh year of his age. He was the second son of the Rev. C. F. Millard, of Norwich, in which city he commenced his professional career, under the auspices of Mr. Crosse. Although young in years, Mr. Millard had acquired great celebrity as a teacher; and it is due to his character to state, that the honourable station to which he had attained was the result of no fortuitous events, but the just reward of talents well directed in the acquisition of professional knowledge, and of integrity of conduct conspicuously evinced in all the relations of private life. Thoroughly master of the subject he had undertaken to teach, and possessing acquirements of a superior order, he was distinguished not only by a degree of industry which has been rarely excelled, but especially by the very lucid and yet comprehensive manner in which he conveyed to his hearers the details of even the most intricate branches of human anatomy. The high estimation in which Mr. Millard was held as a teacher, was some time since evinced by his pupils presenting him with a lasting memorial of their grateful respect.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

May 12, 1836.

John Yates Rutter, Devonport.
Charles Malton.
John Gaskarth, Kendal.
William Baillie, Colchis Estate, Jamaica.
Thomas Robinson Mitchell, Leicester.
John Williams, St. Agnes, Cornwall.
Thomas William Ransom, Stowmarket.

LECTURES ON MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

BY JON. PEREIRA, ESQ., F.L.S.

LECTURE XXXIV.

THERE is a preparation in the London Pharmacopœia termed *precipitated sulphuret of antimony*, which I propose now to examine; but to explain its nature we must take notice of two other compounds closely related to it, namely, *golden sulphuret of antimony* and *kermes mineral*.

Precipitated Sulphuret of Antimony.

History.—Basil Valentine was acquainted with the mode of making precipitated sulphuret of antimony; and, doubtless, must have also known the substance now called *kermes mineral*, though no mention is made of it in his writings. Glauber, in 1658, and Lemery, in 1707, are both said to have discovered the latter substance, but I think it hardly possible for Basil Valentine to have been unacquainted with it.

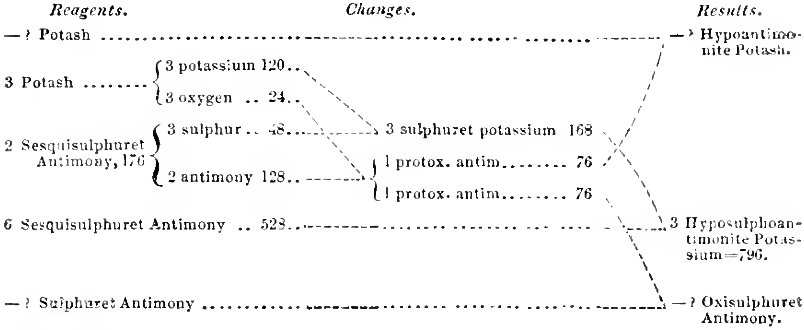
Native state.—There is a mineral called *red antimony*, or *native kermes*, and which is found in Saxony and other places; it is either identical with, or analogous to, one of the present preparations. Rose states its composition to be—

1 atom protoxide antimony	76
2 atoms sesquisulphuret antimony	176
	252

Preparation.—If black sesquisulphuret of antimony be boiled in a solution of caustic potash, a yellowish liquid and a yellowish grey residuum are obtained. The filtered liquor deposits, on cooling, a reddish powder, called *kermes mineral*. If this be separated by filtering, the mother liquor yields, on the addition of an acid, an orange red powder, called the *golden sulphuret of antimony* (*antimonii sulphuretum aurutum*). If the acid be added to the liquid before the kermes mineral has deposited, we obtain the *antimonii sulphuretum præcipitatum* of the Pharmacopœia.

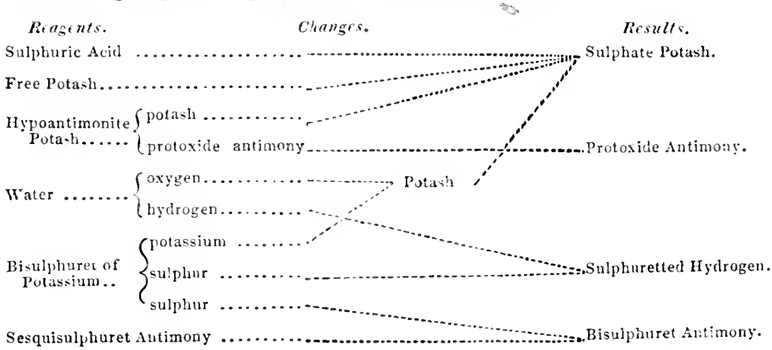
The *theory* of the process is very complicated. From the experiments of Berzelius it appears, that when sesquisulphuret of antimony is boiled with caustic potash, a portion of each of these bodies mutually reacts and produces sulphuret of potassium and protoxide of antimony. Each of these newly formed bodies unites with separate portions of sesquisulphuret of antimony to form two new compounds, namely, *hyposulphoantimonite of potassium*, and an *oxisulphuret of antimony*. Part of the protoxide also unites with some potash, forming a *hypoantimonite of potash*. The following diagram will illustrate these changes:—[*See top of next page.*]

I would remark on this diagram, that the quantity of sesquisulphuret of antimony, with which the sulphuret of potassium combines, varies with the temperature of the liquid. The quantity assigned in the diagram, is, perhaps, the maximum; it is that given by Berzelius as the composition of an antimonial sulphur salt. I am acquainted with no definite hypoantimonite of potash, and, therefore, am unable to fix the quantity of potash which combines with the protoxide of antimony, but it probably varies. Part of this hypoantimonite precipitates, part remains in solution. As the liquid cools, a portion of the sesquisulphuret of antimony which had been held in solution by the sulphuret of potas-



sium, deposits, and, mixing with the precipitated hypoantimonite of potash, constitutes *kermes mineral.*

The liquid from which kermes mineral has separated, contains, in solution, hypoantimonite of potash, and the hyposulphoantimonite of potassium. This last salt, by exposure to the air, undergoes a change; the sulphuret of potassium being converted wholly or partially into bisulphuret, while a little free potash is formed. If now sulphuric acid be added, it unites with this free potash, and with the potash of the hypoantimonite, forming sulphate of potash. Assisted by the elements of water it also decomposes the bisulphuret of potassium, forming sulphate of potash, disengaging sulphuretted hydrogen, and setting free some sulphur. The sesquisulphuret of antimony which was in solution is precipitated, and, at the moment of precipitation, unites with the free sulphur to form bisulphuret of antimony, or the *golden sulphuret of antimony.* The protoxide of antimony of the above mentioned decomposed hypoantimonite, is also converted into an antimonial sulphuret by the sulphuretted hydrogen, separated from the bisulphuret of potassium by the acid. In the following diagram, intended to illustrate some of these changes, I have assumed that all the sulphuret of potassium has been converted into bisulphuret by the oxygen of the air.



Thus, then, I have endeavoured to explain, as briefly as the circumstances allow, the phenomena observed in the manufacture of kermes mineral, and the golden sulphuret. Now, what are the changes in making the *precipitated sulphuret of antimony* of the Pharmacopœia? Evidently they must be a combination of those for making kermes mineral and the golden sulphuret. By boiling the sesquisulphuret of antimony with caustic potash, the phenomena must be the same as described and illustrated by the first diagram. When sulphuric acid is added, we shall obtain sulphate of potash in solution, sulphuretted hydrogen gas will be evolved, and sesquisulphuret of antimony, mixed probably with some protoxide, will be precipitated.

Composition.—No analysis has been made of the precipitated sulphuret of antimony. Various analyses of kermes mineral, and of the golden sulphuret of antimony, are frequently quoted as being analyses of this preparation. These three preparations differ from each other, though each, probably, is liable to some variation.

1. *Kermes mineral* may be regarded as consisting essentially of the *sesquisulphuret of antimony*, but mixed with the *hypoantimonite of potash*.

According to Buchner, kermes mineral, when deprived of its hygroscopic water by drying, consists of—

2 atoms sesquisulphuret antimony	176
1 atom protoxide antimony	76
1 atom water	9
	261

In this analysis you will observe that he omits all notice of the potash, which, according to Berzelius, is in combination with the protoxide of antimony. M. Henry, Jun., has also analysed kermes mineral, and he obtained the same relative proportions of sesquisulphuret and oxide of antimony. Buchner thinks, that in the above preparation the sesquisulphuret performs the function of an acid (which he terms the *stibiothionic acid*) and that the protoxide of antimony is the base. So that, according to his notions, kermes mineral is the *hydrated stibiothionate of antimony*.

2. *Golden sulphuret* contains more sulphur. According to the time the liquid has been exposed to the air before the acid is added, it may contain more or less *bisulphuret of antimony*, or even the *persulphuret*. It contains no potash, but usually some *protoxide of antimony*.

Thenard, some years since, analysed this preparation; the following are his results:—

Sulphur	12·00
Sulphuretted hydrogen ..	17·87
Protoxide antimony	68·30
Loss	1·83
	100·00

Now, if we assume that the hydrogen of the sulphuretted hydrogen was obtained by the decomposition of water, the analysis would stand thus:—

Persulphuret antimony ..	72·874
Protoxide antimony	15·046
Water	9·460
Sulphur	0·790
Loss	1·830
	100·000

This is about $3\frac{1}{2}$ atoms persulphuret of antimony to 1 atom of the protoxide.

3. *Precipitated sulphuret of antimony* must consist principally of the *sesquisulphuret*, with, perhaps, a little of the *bisulphuret* and *protoxide of antimony*. It can contain no potash.

Characteristics.—These three preparations are known by their more or less reddish colour, and by yielding sulphuretted hydrogen and chloride of antimony when digested in hydrochloric acid.

Physiological effects.—The general operation of these three preparations is similar, though probably somewhat different in degree. The effects they produce are analogous to those already detailed when speaking of tartar emetic, the action of which is, however, much more certain, on account of its composition being definite. In *large doses* these preparations act as irritant poisons, producing gastro-enteritis, indicated by pain, vomiting, purging, &c. In more *moderate doses* they excite nausea and vomiting, and might be employed for this purpose in the absence of tartar emetic, or other more certain emetics. In *smaller* doses they are said to be sudorific, expectorant, and alterative. Rayer states that no obvious effects were produced by the application of one or two drachms of either kermes mineral, or the golden sulphuret, to a wound made in the thigh of a dog. He states also, that two of his pupils, Dr. Bisson and M. Raisin, never experienced from the use of kermes mineral on themselves, sweating, cough, or any other symptom indicating its action on the skin or respiratory organs. Rayer, however, admits he has seen sweating produced by the golden sulphuret.

These different preparations owe their activity principally or wholly to the protoxide of antimony which they contain. Rayer states that the golden sulphuret is less active than kermes mineral; doubtless because it contains less protoxide of antimony. The precipitated sulphuret of the London Pharmacopœia may be regarded as of intermediate strength.

Uses.—As *emetics* we rarely or never employ them.

As *antiphlogistics*, or *contra-stimulants*, they have been used in the same cases as tartar emetic. Thus kermes mineral has been recommended in inflammatory affections of the respiratory organs; for example, laryngitis, bronchitis, and pneumonia; though some refer the beneficial influence said to have been observed in these diseases, to the *expectorant* effects. They have also been employed in rheumatism, as *sudorifics*. The precipitated sulphuret of antimony is principally employed in this country as an *alterative* in chronic diseases, particularly cutaneous affections, glandular enlargements, secondary syphilis, and diseases of the liver.

Administration.—As an *alterative*, the precipitated sulphuret is usually exhibited in combination with mercury, as in the *pilulæ hydrargyri submuriatis compositæ*, Ph. Lond. (usually denominated *Plummer's pill*,) and

which consists of calomel, precipitated sulphuret of antimony, and guaiacum. Four grains of this contain about one grain of calomel, and one of the sulphuret; and the usual dose, as an alterative, is from 5 to 10 grains. Kermes mineral, in doses of from 4 to 8 grains, usually vomits and purges; the golden sulphuret is not quite so active.

Proto-chloride of Antimony.

History and synonymes.—The preparation was known to Basil Valentine. It has had various appellations, such as *oil* or *butter of antimony*, *muriate of antimony*, &c.

Preparation.—The butter of antimony of the shops is prepared by dissolving crude antimony (that is, fused native black sulphuret) in muriatic acid. The results of this operation are the proto or sesquichloride of antimony and sulphuretted hydrogen.

Re-agents.	Results.
$\underline{\overset{\prime\prime\prime}{S}b}$	$3\,\dot{H}$
$3\,(H\;Chl)$	$\underline{Sb}\;3\,Chl$

Properties.—As usually met with in the shops, it is a deep red liquid, which fumes in the air (in consequence of an excess of acid). Its specific gravity varies from 1·2 to 1·5.

Composition.—It is essentially composed of

1 atom antimony	..	= 64
$1\frac{1}{2}$ atoms chlorine	..	= 54
		118

Hence its symbol is $\underline{\overset{\prime\prime\prime}{S}b}$

The liquid chloride of the shops contains water, and usually excess of muriatic acid. It may contain, also, impurities derived either from the sulphuret, or from the acid: thus it frequently contains chloride of iron. Serullas says he never found arsenic in it.

Characteristics.—When water is added to it, a yellowish-white precipitate, called the *powder of Algaroth*, (or *mercury of life*) is formed. Sulphuretted hydrogen, or the hydro sulphurets, produce an orange-red precipitate of the sesquisulphuret of antimony. The alkalies throw down the protoxide of this metal. Nitrate of silver occasions a white precipitate of the chloride of silver, and oxide of antimony: the latter may be removed from the chloride of silver, by digestion in muriatic acid. In some respects this liquid agrees with liquid muriatic acid; thus, in its acid and corrosive properties, and in its fuming in the air: the fumes redden litmus paper, and are increased by the presence of ammonia.

Physiological effects.—Butter of antimony of the shops is a powerful caustic; and, therefore, if swallowed, would act as a corrosive poison, though I am not acquainted with any instances in which it has been used as a poison in the human subject.

Uses.—In medicine it is employed as a caustic, and to yield the powder of Algaroth, which is sometimes used in the manufacture of tartar emetic. As it is decomposed by dilution, it is never administered internally. Like the mineral acids, its liquidity renders it, in some cases, objectionable as a caustic, but in others advantageous. It usually acts without very much pain or inflammation; and after the separation of the eschar, a clean healthy surface is generally observed. It is sometimes used as an application to bites of rabid animals, or of venomous snakes, its liquidity enabling it to penetrate into all parts of the wound. It is applied to ulcers to repress excessive granulations. Richter and Beer have employed it in that form of enlarged and opaque condition of the cornea called staphyloma, with the view of improving the form of the cornea; for it is impossible to restore its transparency. The mode of using it is this:—dip a camel's hair pencil, or a point of lint, into the chloride, and apply to the part until you observe a whitish appearance: then immediately wash it off (by means of another larger pencil) with milk, and afterwards with milk and water.

Antidotes.—In a case of poisoning by this liquid, you should immediately administer alkaline substances (as chalk, magnesia, or soap) to neutralize the excess of acid; in other words, adopt the treatment I have already directed for poisoning by the strong acids. Afterwards, with the view of neutralizing the effect of the oxide of antimony which would be separated in the stomach, administer astringents as in the case of poisoning by tartar emetic. The gastro-intestinal inflammation should be combatted by the usual means.

The next metal which I shall notice is

BISMUTH.

The only pharmacological preparation of this, is the

Subnitrate of Bismuth.

History and synonymes.—This compound was first prepared by Lemery. It has had various appellations, such as *pearl* or *flake white*, *magistery of bismuth*, *Spanish white*, and *tetarto-nitrate of bismuth* (the name given it by Dr. Thomson).

Preparation.—It is prepared by dissolving one ounce of bismuth in a fluid ounce and a half of nitric acid, to which six drachms of water have been added. After the solution has been filtered, about three pints of distilled water are to be added: the subnitrate precipitates, and is to be collected, washed, and dried.

Part of the nitric acid oxidizes the bismuth, binoxide of nitrogen escaping. The oxide thus formed unites with some undecomposed nitric acid, to form nitrate of bismuth.

Reagents.	Results.
$4\ \overset{\cdot\cdot\cdot\cdot\cdot}{N}$	$\ddot{N}$
$3\ Bi$	$3\ (\dot{Bi}\ \overset{\cdot\cdot\cdot\cdot\cdot}{N})$

When water is poured into the solution of nitrate of bismuth, two other salts of bismuth are formed—namely, a soluble supersalt and an insoluble subsalt.

Reagents.	Results.
$5\ (\dot{Bi}\ \overset{\cdot\cdot\cdot\cdot\cdot}{N})$	$\dot{Bi}\ 4\ \overset{\cdot\cdot\cdot\cdot\cdot}{N}$
	$4\ \dot{B}\ \overset{\cdot\cdot\cdot\cdot\cdot}{N}$

Properties.—It is a dull, white, inodorous, tasteless powder, which consists of very fine silky needles. It is nearly insoluble in water, but is readily dissolved by nitric acid. By exposure to light it becomes greyish.

Composition.— According to Grouvelle, the silky needles of this salt consist of

1 atom nitric acid	....	54
4 atoms oxide of bismuth	$(80\times 4) =$	320
2 atoms water	$(9\times 2) =$	18
		292

The formula for this compound is, therefore,

$$4\ \dot{Bi}\ \overset{\cdot\cdot\cdot\cdot\cdot}{N}\ 2\ \dot{H}$$

Characteristics.— Sulphuretted hydrogen, or the hydrosulphurets, blacken it, by forming the sulphuret of bismuth. It dissolves in nitric acid without effervescence, by which it is easily distinguished from carbonate of lead. Heated on charcoal by the blowpipe flame, it gives out nitrous acid, and yields the yellow oxide of bismuth; and by a continuance of the heat the oxide is reduced, globules of metallic bismuth being obtained, which may be readily distinguished from globules of lead by their brittleness; for when struck sharply by a hammer on an anvil, they fly to pieces: from antimony they are distinguished by their solubility in nitric acid.

Physiological effects. — When applied to wounds, or taken in *excessive quantity* into the stomach, it acts as a powerful local irritant, and, in the latter case, gives rise to all the symptoms indicative of gastrointestinal inflammation, and which I have so frequently mentioned, in speaking of other irritant poisons. After death, the usual appearances of inflammation and its consequences are observed. I am only acquainted with one case in which it proved fatal in the human subject; the quantity taken was two drachms, and death occurred on the ninth day. I may just notice, that, in addition to the usual symptoms of gastro-enteritis, there was disorder of the nervous system, indicated by the cramps of the hands and feet, the disordered vision, and delirium. It is deserving also of remark, that there were present difficulty of breathing, and salivation. Post-mortem examination showed inflammation throughout the alimentary canal; the spinal vessels were gorged with blood, particularly towards the cauda equina; there was fluid in the cerebral ventricles; and the inner surface of both ventricles of the heart was very red.

If taken in *large doses as a medicine,* it disorders the digestive organs, occasioning pain, vomiting, purging, &c.; and sometimes it affects the nervous system, producing giddiness, insensibility, cramps of the extremities, &c. In *small doses* it acts locally as an astringent, diminishing secretion. On account of the frequent relief given by it in painful affections of the stomach, it is supposed to act on the nerves of this viscus as a sedative. It has also been denominated tonic and antispasmodic. Vogt says, that when used as a cosmetic, it has produced a spasmodic trembling of the muscles of the face, ending in paralysis. We have not at present sufficient evidence to determine whether this medicine affects the general system by absorption or through the intervention of the nervous system: its insolubility has led to the conclusion that it does not become absorbed.

Use.—It has been principally employed in those chronic affections of the stomach which are unaccompanied with any organic disease, but which apparently depend on some disordered condition of the nerves of this viscus; and hence the efficacy of the remedy is referred to its supposed action on these parts. It has been particularly used and recommended to relieve gastrodynia—to allay sickness and vomiting, and as a remedy for the water-brash. It has also been employed in intermittent fever, in spasmodic asthma, &c. Hahnemann has recommended a portion to be introduced into a hollow tooth, to allay tooth-ache. I have used it, with

advantage, in the form of ointment, applied to the septum nasi, in ulceration of this part, and as a local remedy in chronic skin diseases.

Administration.—The usual dose of this remedy is from five grains to a scruple, exhibited in the form of a pill. The ointment which I have just referred to was composed of one drachm of the subnitrate, and half an ounce of spermaceti ointment.

Having now concluded all the remarks I think it necessary to make respecting the electro-negative metals and their compounds, I proceed to the third and last division, containing those metals which are *electro-positive* in saline combinations, but whose oxides neither form alkalies nor earths. The first of this division which I shall notice, is

TIN.

The only pharmacological preparation of this metal is

Powdered Tin.

Tin was employed by Paracelsus as a vermifuge; as also against dropsy and jaundice. Alston, however, may be regarded as having introduced it, as an anthelmintic, in modern practice.

Preparation.—Tin is used in medicine in two states—either as *filings* (*limatura stanni*), or *granulated* (*stannum granulatum, pulvis seu scobs stanni*). Of the preparations of the filings I need say nothing. Granulated or powdered tin may be prepared by melting the metal in an iron ladle, and stirring with an iron pestle; or pouring it into a wooden box, rubbed on the inside with chalk, and shaking it until cold. Another method is, to melt tin in an iron pot, and stir with a birch-broom. The finer are then to be separated from the coarser particles, by a sieve. There are five kinds of tin met with in commerce—namely, two imported from the East (*Malacca tin*, met with in quadrangular pyramids, and *Banca tin*), two obtained in Cornwall—namely, *grain tin* and *block tin* (the latter, when purified, is called *refined block tin*); and, lastly, an impure *German tin* is also met with. Grain tin, as being the purest kind of Cornish tin, should be employed for granulation.

Properties.—Tin, in its massive form, is a yellowish-white metal, emitting a peculiar odour when rubbed or handled. When quite pure, its specific gravity is 7·28 or 7·29. It melts at 442° Fahr.; its atomic weight is 58.

Powdered or *granulated tin* has but little brilliancy, and probably is slightly oxidized.

Characteristics.—Dissolved in strong muriatic acid, we obtain a protochloride of tin, which is readily recognized, first by sulphuretted hydrogen causing with it a brown precipitate of the protosulphuret of tin; and, secondly, by the chloride of gold, which occasions the formation of the purple powder of Cassius. If the protochloride of tin be boiled with a little nitric acid, it is converted into the perchloride, which may be recognized by the yellow precipitate occasioned with sulphuretted hydrogen.

Physiological effects.—In the mass, tin has no operation on the body, except that arising from its form and weight. Powdered tin is not known to produce any disorder in the functions of the body. It appears, however, that acid, fatty, saline, and even albuminous substances, may occasion colic and vomiting, by having remained for some time in the vessels.

Uses.—Powdered tin has been employed with great success by various eminent practitioners, as a vermifuge, particularly in tape-worm. Dr. Alston explains its operation on mechanical principles: he supposes the powder of tin gets betwixt the worms and the inner coat of the alimentary canal, and causes them to quit their hold, so that purgatives easily carry them away with the fæces. It has, however, been asserted that water in which tin has been boiled is anthelmintic, at least so says Pitcairn and Pietsch; wine which has been digested in a tin vessel is also said to be noxious to worms. If these statements be true, the before-mentioned mechanical explanation is inadmissible. Some have, therefore, supposed that the efficacy must depend on the tin becoming oxidized in the alimentary canal; others have fancied that arsenic, which is frequently found in tin, is the active agent; while, lastly, some have imagined the metal, by its action on the fluids of the canal, generated hydrogen, or sulphuretted hydrogen, which destroyed these parasites.

Monro, Fothergill, and Richter, have used powdered tin in epilepsy, and, as is stated, with advantage.

Administration.—The usual mode of exhibiting it is mixed with treacle: the dose stated in books is one or two drachms, but Alston gave much larger quantities; his mode of employing it as a vermifuge was the following: — The patient was well purged with senna, and on the following morning *one ounce* of tin powder was given in four ounces of treacle; on each of the two following days half this quantity was taken, and then the patient again purged. However, tin powder is certainly much inferior to oil of turpentine as a remedy for tape worm.

I proceed now to notice another metal of this division, namely,

ZINC, OR SPELTRE.

Several preparations of this mineral are employed in medicine—namely, the *oxide*, the *chloride*, the *sulphate*, the *acetate*, and *cyanuret*. Of these I shall first notice the

Oxide of Zinc.

History and synonymes.—Hellot, in 1735, is said to have first prepared this oxide in the pure state, by burning the metal. It has received various appellations, some of a fantastic nature, such as *nihil album*, *lana philosophica*, *pompholyx*, *flowers of zinc*, &c.

Native state.—The mineral called *red zinc*, found in America, is a compound of oxide of zinc, and sesquioxide of manganese (Thomson says 7 atoms of the first to 1 of the second.) *Voltzinc*, or the oxisulphuret of zinc, is composed of sulphuret with some oxide of zinc. Oxide of zinc is also found combined with carbonic, silicic, and sulphuric acids.

Preparation.—It is readily prepared by precipitation from the sulphate of zinc. Any of the alkalies will do as precipitants, but in the London Pharmacopœia ammonia is ordered. The alkali employed abstracts the sulphuric acid from the sulphate, setting at liberty the oxide. Care must be taken not to use too much alkali, which would redissolve the oxide; for this oxide is capable of performing the function of an acid when placed in contact with the strong alkalies; that is, of combining with them.

Reagents.	Results.
$\dot{Zi}\,\dddot{S}$	Am. $\dddot{S}$
Am.	$\dot{Zi}$.

This oxide may also be procured by the combustion of the metal.

Properties.—As ordinarily met with it is a light flocculent white powder; but when heated becomes yellow. It is odourless and tasteless: when heated it fuses, and forms a yellow kind of glass. It is insoluble in water, but very soluble both in acids and alkalies: with the first it forms the *oxisalts of zinc*; with the latter, a class of compounds which may be termed *zincates*. It is easily reduced to the metallic state, by heating it in contact with carbonaceous compounds.

Composition.—Oxide of zinc is composed of—

1 atom of zinc	=	34
1 atom of oxygen ..	=	8
		42

Its symbol, therefore, is $\dot{Zi}$.

As thrown down from the salts of zinc by an alkali, it is a hydrate, and consists of—

1 atom oxide zinc ..	=	42
1 atom water	=	9
		51

Its symbol is $\dot{Zi}\,\dot{H}$.

Characteristics.—If dissolved in an acid the zincic solution has the following characters:—Ferrocyanuret of potassium occasions a white gelatinous precipitate (ferrocyanuret of zinc); sulphuretted hydrogen (if the zincic solution be neutral) occasions a white precipitate (sulphuret of zinc). The alkalies produce a white precipitate (the hydrated oxide), soluble in an excess of the precipitant.

Physiological effects.—The effects of oxide of zinc on the body are not very obvious. Orfila tried it on dogs in doses of from three to six drachms, and the only effect noticed was vomiting; so that it cannot be termed a poison. Applied to ulcerated surfaces it is regarded as desiccative and astringent. Taken internally, in large doses it is emetic; in smaller doses it is termed tonic and sedative, and is supposed, by continued use, to exert some influence over the nervous system, though this is not very obvious. It is, in fact, one of the feeblest of the zincic preparations.

Uses.—Used as a *dusting powder*, it is serviceable from its mild absorbent and desiccative properties, in impetiginous and other chronic diseases of the skin attended with a copious discharge,—to allay or prevent excoriation in children and bedridden persons,—to diminish the discharge and allay pain in ulcers, and sometimes as an application to the eyelids in affections of those parts accompanied with much discharge, &c. Frequently the oxide is *diffused through water* or a mucilaginous solution, and used in this way as a collyrium in affections of the eyelids. Lastly, an *ointment of zinc* is employed as a mild cooling desiccative application, in various skin diseases, particularly those accompanied with discharge, as impetigo and porrigo; after extensive burns or irritant applications (as blisters, sinapisms, &c.); to painful ulcers, especially those attended with much discharge; to the eyelids, in chronic inflammation of these parts.

Internally oxide of zinc has been principally employed in affections of the nervous system; for example, chorea, epilepsy, catalepsy, hysteria, neuralgia, &c. But used in this way it is a remedy of little or no value. Very recently a case has been published by M. Bonifacio Chiovitti, in a Neapolitan journal, in which the oxide of zinc was advantageously administered to a mare poisoned by extract of belladonna.

Administration.—As an *external* application a drachm or two may be diffused through six or eight ounces of water, or thin mucilage; or we may use it in the form of ointment, composed of one drachm of the oxide to six drachms of lard. *Internally* it is given in doses of from two to eight or ten grains, either in the form of pill, or mixed up with treacle, or some thick substance of this kind.

Tutty.

Tutty, tutia, or *tuthia,* called also *cadmia factita,* or *cadmia fornacum,* is an *impure oxide of zinc,* found in the chimney of the furnace in which zinc ores are roasted, or in which lead ores containing zinc are smelted. When levigated it forms the *prepared impure oxide of zinc,* or *prepared tutty* of the shops. It is made into ointment, which is used in the same cases as the zinc ointment already mentioned.

Chloride of Zinc.

History and synonymes.— *Chloride, muriate,* or *butter of zinc* (for by all of these names has it been designated), has been known for a long period. It was first, I believe, introduced into medicine by Papenguth, and subsequently has been recommended by Professor Hauke, of Breslau, and by Dr. Canquoin, of Paris. A full account of the use of it by the latter has been given by Mr. Ure, in the 17th volume of the MEDICAL GAZETTE.

Preparation.—The easiest and cheapest method of obtaining it is by dissolving zinc, or its oxide, in muriatic acid, evaporating to dryness, and fusing in a glass vessel with a narrow mouth, as a Florence flask.

Properties.—It is a whitish grey, semi-transparent mass, having the softness of wax. It is fusible, and at a strong heat it may be sublimed and crystallized in needles; it is very deliquescent; it unites with both albumen and gelatine to form difficultly soluble compounds, and hence it occasions precipitates with albuminous and gelatinous liquids.

Composition.—It is composed of—

1 atom chlorine	36
1 atom zinc	34
	70

Characteristics. — Dissolved in water it may be recognized to be a chloride or muriatic salt by nitrate of silver, as already mentioned when speaking of muriatic acid. That zinc is the base of the salt may be shewn by the tests mentioned for the oxide of zinc.

Physiological effects.—Its *local* action on living tissues is that of a caustic, or escharotic, depending partly, as Mr. Ure thinks, on its affinity for albumen and gelatine: so that when placed in contact with living parts into whose composition these organic compounds enter, it is supposed that the chloride exercising its affinity, first destroys the life of the parts, and then unites with the albuminous and gelatinous matters present, and forms thus an eschar. Other chemical changes of a comparatively unimportant nature are also effected: thus various salts found in the solids or liquids of the part may be decomposed. For example, when the chloride is applied to a cancerous sore, it will decompose the carbonate, and hydrosulphuret of ammonia is said to be found in the secretion of the sore. The effects produced by the application of chloride of zinc are the following:—soon after it has been applied, a sensation of warmth is felt in the part, quickly followed by violent burning pain, which continues for 7 or 8 hours; that is, until the parts in contact with the chloride are dead. If the part be now examined, a white eschar is observed, which usually separates in from 8 to 12 days. Unless used in the neighbourhood of loose cellular tissue, there is rarely much swelling.

As a caustic, chloride of zinc is not inferior in power to chloride of antimony; nay, Vogt says, it appears to him to be more powerful, and to penetrate deeper. It decomposes the organic tissues as quickly as the nitrate of silver, but excites more burning, and for a longer time, owing to its action extending to parts placed more deeply, for it is well known that the operation of the nitrate is confined to superficial parts. Both Vogt and Canquoin agree that chloride of zinc, besides corroding the parts with which it is in contact, exercises an influence over the vital actions of neighbouring parts. To this circumstance is owing, in great part, the efficacy of the chloride in various diseases in which it has been applied, (cancer, for example) and the healthy appearance of the sore after the separation of the eschar. There is no danger of any constitutional disorder arising from the absorption of the poison, as is the case with the arsenical and mercurial caustics.

Taken *internally,* in *large doses,* it acts as an irritant or caustic poison, and affects the nervous system. Thus it produces a burning sensation in the stomach, nausea, vomiting, anxiety, short breathing, small quick pulse, cold sweats, fainting, and convulsions. Taken in *very small doses,* no obvious effects are produced, except sometimes the amelioration of certain diseases. It is supposed in these cases to influence the nervous system.

Uses.—*Internally* chloride of zinc has been given in small but gradually increased doses in scrofula, epilepsy, chorea,

and (in combination with prussic acid) in neuralgia of the face. Commonly, however, it is employed *externally*: thus Papenguth used it as a lotion in fistulous ulcers of a scrofulous nature. As a *caustic* it has been applied by Professor Hanke and Dr. Canquoin in various cases: thus it has been used to produce an issue, to destroy nævi materni, and as an application to parts affected with malignant diseases, such as fungus hæmatodes and cancer, or to other intractable forms of disease, such as old syphilitic or scrofulous ulcers. The benefit is supposed not to depend merely on the escharotic effect, but on the chloride inducing a new action in the surrounding parts.

Administration. — *Internally* it may be given in doses of one or two grains. Hufeland recommends it to be taken dissolved in æther; his formula for the *æther zinci*, as it is called, is the following:—

> ℞ Zinci Chlor. ʒss.; Alcoholis, ʒj.; Ætheris Sulph. ʒij. Post aliquot dies decanta.

The dose of this solution is from four to eight drops, taken twice daily.

Externally it has been used as a *lotion*, composed of two grains of the chloride and an ounce of water; or in the form of *paste*. This may be composed of one part chloride of zinc, and from two to four parts of wheaten flour.

Sulphate of Zinc.

History and synonymes.—This salt is said by Schwartz to have been known towards the end of the 13th, or at the commencement of the 14th century; but Beckmann affirms it was not known before the middle of the 16th century. It has had various names, as *white vitriol*, and *Gilla Theophrasti*.

Native state.—This salt occurs native at Rammelsberg, near Goslar, in the Harz; at Holywell, in Flintshire, and other places.

Preparation.—It is readily prepared by dissolving zinc in dilute sulphuric acid. The solution is to be filtered, evaporated, and crystallized. In this process the water is decomposed, its hydrogen escapes, while the oxygen unites with the zinc; and the oxide thus formed combines with some sulphuric acid to form the sulphate.

Reagents.	Results.
$\dot{H}$	H
Zi	$\dot{Zi}\,\dddot{S}$
$\dddot{S}$	

By roasting ores containing native sulphuret of zinc an impure sulphate is obtained, usually distinguished among druggists by the name of *white vitriol*, a term which they confine to this commoner kind of sulphate. This process yields an impure salt, which generally contains iron, or even copper or lead.

Properties.—The primary form of the crystals of this salt is the right rhombic prism: they are transparent and colourless, and have a metallic astringent taste. They are soluble in $2\frac{88}{100}$ times their weight of cold water, and less than their own weight of boiling water.

Composition.—This salt is composed of

1 atom oxide zinc	42
1 atom sulphuric acid ..	40
7 atoms water .. $9 \times 7 =$	63
	145

Its symbol is, $\dot{Zn}\ \dddot{S}\ 7\dot{H}$

Characteristics.—That this salt is a sulphate, is proved by the action of chloride of barium on it; a white precipitate is produced, insoluble in nitric acid. In order to prove that the base of the salt is oxide of zinc, the tests already mentioned under the head of the oxide may be employed.

Physiological effects. — In *small repeated* doses, sulphate of zinc is accounted tonic; but it may be taken for a considerable time without any obvious effect on the functions of the body, as I have several times seen. It is presumed, however, that it influences the nervous system, and to this influence is attributed the benefit obtained in certain diseases. In *full doses* it excites speedy vomiting, without giving rise to the same degree of nausea produced by the antimonial emetics. Occasionally, when *very large* quantities have been swallowed, symptoms of poisoning have been observed—namely, vomiting, purging, coldness of the extremities, and fluttering of the pulse. The *local* effects of this salt are astringent.

Uses. — As an *emetic* it is used in cases of narcotic poisoning, partly on account of its speedy operation, and in part, also, on account of its producing comparatively little nausea. Whenever our object in exciting vomiting is merely the evacuation of the stomach, this is as good an emetic as can be employed; but when we wish to influence diseases by the impression made on the system, tartar emetic is preferable. In small doses (some say as a *tonic* or *antispasmodic*) it is used with occasional success in epilepsy, chorea, and ague. As an *astringent*, also, in discharges from the mucous membranes. Its principal use is as an *external* application,—as a collyrium in chronic ophthalmia, to diminish the discharge—as a wash to ulcers—or as an injection in gleet and leucorrhœa.

I have seen a solution of one drachm of the sulphate to an ounce of water used as an injection in gleet with the best effects.

Dose.—As an emetic, from grs. x. to grs. xx. are exhibited; as a tonic, from gr. j. to gr. v. As an external application, an aqueous solution is used of various strengths, from gr. j. and upwards, to the ounce of water.

Acetate of Zinc.

History and synonymes.—This salt was discovered by Glauber.

Preparation.—It may be procured by dissolving zinc or its oxide in acetic acid, and crystallizing the saturated solution. Or, it may be readily obtained by double decomposition: 145 grains of crystallized sulphate of zinc dissolved in water and added to 190 grains of the acetate of lead, in solution, will just produce 152 grains of sulphate of lead, which, being insoluble, precipitates, while 93 grains of the anhydrous acetate of zinc (equal to 156 grains of the crystallized acetate) will be left in solution.

Re-agents.	Results.
$\dot{Zi}\ \dddot{S}$	$\dot{Zi}\ \overline{A}$
$\dot{Pb}\ \overline{A}$	$\dot{Pb}\ \dddot{S}$

Properties.—The primary form of the crystals of this salt is the oblique rhombic prism. The salt has a bitter metallic taste, and dissolves readily in water.

Composition.—It consists of—

1 atom oxide zinc	42
1 atom acetic acid...........	51
7 atoms water 9×7	63
	156

Its formula, therefore, is—$\dot{Zi}\ \overline{A}\ 7\dot{H}$

Characteristics.—It carbonizes when heated: when sulphuric acid is added to the salt, it evolves acetic acid, which is easily recognised by its odour. These characters show it to be an acetate. That it is a zincic salt is proved by the tests mentioned for the oxide of zinc.

Physiological effects.—Its effects, when taken internally, are milder, though analogous to those produced by the sulphate. We have no evidence as yet, however, of its capability of acting as a poison, though if *very large* quantities were swallowed, it is not unlikely that gastro-enteritic irritation, or inflammation, might be brought on. Full, or even *large* doses, excite vomiting, and act slightly as purgatives. It appears also, that the continued use of *small doses* has no injurious effect on the constitution; but an effect is supposed to be produced on the nervous system, which is said to be serviceable in several diseases.

The local operation of the acetate of zinc is that of an astringent, more powerful than that of the oxide, but less so than that of the sulphate of zinc.

Uses.—It is rarely employed *internally*, but is applicable to those cases which are treated by the oxide or sulphate, since its power is intermediate. The dose of it is from 2 or 3 grains to 8 or 10 grains. It is much more frequently used as an *external* application, as a collyrium in ophthalmia, or as an injection in gleet and leucorrhœa. The strength of the solution may be two or three grains to the ounce of water, or much stronger than this.

Native Carbonate of Zinc.

History and native state.—*Lapis calaminaris* seems to have been known to the ancient Greeks, though they were unacquainted with its nature. Under this name are included several mineral species, such as anhydrous carbonate, hydrous dicarbonate, and silicate. That which is used in medicine is the *anhydrous carbonate*, which is found abundantly in several parts of this country, for example, the Mendip hills; Somersetshire, Derbyshire, Durham, &c.

Preparation.—Native anhydrous carbonate of zinc, called impure carbonate of zinc, or calamine, is first calcined, then powdered, and is afterwards reduced to a very fine powder by elutriation. In this state it constitutes the *calamina præparata* of the Pharmacopœia.

Properties.—Prepared calamine is met with in the shops in the form of a reddish yellow powder, or made up into little masses, and having an earthy appearance.

Composition.—The native anhydrous carbonate of zinc is composed, according to Mr. Smithson, of—

	Specimen from Somersetshire.	Specimen from Derbyshire.		
Carbonic acid	35·2	34·8	or	1 atom = 22
Oxide of zinc	64·8	65·2		1 atom = 40
	100·0	100·0		62

Physiological effects and uses.—It is a very mild agent, probably similar to the oxide of zinc in its operation. It is used externally as a dusting for children, and is a most excellent application for this purpose, there being no danger attending its use, as

in the case of the carbonate of lead, which is sometimes substituted. There is a very useful cerate (commonly termed *Turner's cerate*) made of half a pound prepared calamine, half a pound of yellow wax, and a pint of olive oil. It is called in the Pharmacopœia *ceratum calaminæ*, and is a most valuable cooling application after burns, scalds, or to ulcers or excoriations.

Dose.—From one to four grains.

Cyanuret of Zinc.

History.—This salt, called also *hydrocyanate of zinc*, has been introduced by the German physicians as a substitute for hydrocyanic acid.

Preparation.—To procure pure cyanuret of zinc, the best method is to add oxide of zinc to hydrocyanic acid.

Properties.—Cyanuret of zinc is a white powder, insoluble in water or alcohol.

Composition.—It consists of—

1 atom cyanogen	26
1 atom zinc	34
	60

Characters.—If a strong mineral acid be added, hydrocyanic acid is developed. That it is a zincic salt is determined by the tests mentioned for the oxide of zinc.

Physiological effects.—Its effects have not been well ascertained, but they have been supposed to be similar to hydrocyanic acid.

Uses.—It has been used principally in affections of the nervous system: thus epilepsy, hysteria, and chorea. It has also been employed in cardialgia and cramps of the stomach, and as an an anthelmintic.

Administration.—We may give from a quarter of a grain to a grain and a half three times a day.

REPORT ON THE MEDICAL INSTITUTIONS OF IRELAND.

By Wm. P. Borrett, M.D.
Assistant-Commissioner for inquiring into the state of the Irish poor.

(*Communicated by the Author.*)

PART I.—ON THE DISPENSARIES.

[Continued from p. 257.]

The Dispensaries are supported by voluntary contributions and by assessments upon the county, upon the principle of making private charity indispensable in order to obtain a great public grant. But however excellent in theory such a plan may appear to be, it has not succeeded well in practice.

Indeed, the collecting of private subscriptions seems generally to fail in Ireland. The higher orders, for the most part, enter but little into the feelings of the poor, and the appeal of suffering humanity to private benevolence is too often made in vain. There are, of course, many most exemplary acts of generosity on the part of the rich; but while there are some who invariably give, there are others who invariably refuse, and persons who have been employed to collect subscriptions for the support of charitable institutions, or in the times of distress, know full well those who will assist, and those who will not. It is hardly worth while, they will tell you, to apply to the latter class, so systematically and pertinaciously do they refuse all petitions, and yet they are frequently the persons best able to give. The medical gentlemen, who attend at the Dispensary at Tralee, give their services gratuitously, and yet the gentry will not subscribe money enough to pay for medicines. In almost a total absence of subscriptions last year the players kindly came forward, and offered the proceeds of a night's performance in aid of the charity. Thirteen pounds were thus raised, to which the Board of Health added ten, and then the Grand Jury were called upon to contribute a donation equal to the amount procured.

There is a like dearth of subscriptions towards the Fever-hospital and Infirmary at Tralee, which are almost entirely supported at the public expense. At Bantry, Kilworth, Kenmare, &c. &c. it was stated there were gentlemen possessed of 1000*l.* to 2000*l.* per annum, in the district, who refused to subscribe to the Dispensary, although its operations were crippled for want of funds. At Castletown Roche, the names of as many as fifteen persons were given, enjoying incomes from landed property in the neighbourhood, of 500*l.* to 5000*l.* per ann., who contributed nothing to the support of the Dispensary, but left their dependants to get relieved upon the orders of others. Even with actual subscribers, the contributions do not bear that proportion to their respective means and resources which might in fairness be expected from them. At Ballylongford there were eight large landed proprietors in the district, whose united subscriptions amounted only to twelve pounds. Men possessing some thousands a year subscribe but an annual guinea, as that sum entitles them to as many tickets as they want; while those who do not subscribe at all, insist upon the needlessness of becoming subscribers, when their dependents can easily procure tickets in some other quarter.

The above are not extraordinary in-

stances. The indisposition to subscribe is general; but it has its exceptions, as I have already remarked, and these sometimes very splendid ones. Nevertheless, the charitable intentions of the subscribers who contribute liberally for the support of the Dispensaries, are too often abused. Most of those who are living upon their estates, whether proper or improper objects, consider they have a right to be supplied with medical advice and medicine; so that, in such a case, more than the full worth is had for the money subscribed. Hence it is that virtually the public institutions are made subservient to private ends, by the very means which are ostensibly for the public interest.

Although it is forbid, on the one hand, to grant assistance from the public purse when there are no local private contributions, that assistance is made absolute, upon the other, on the amount of subscription being certified. The law, in its present state, affords an opportunity to any person, or number of persons, to get up a Dispensary, whether it be for his or their accomodation, or for that of the public. Whether it be paid by the medical man who wants an appointment, or by a gentleman who is desirous to establish a medical practitioner in the neighbourhood, to attend upon his own family or his tenants—if only a certain sum be raised by private resources, to be applied for the maintenance of a Dispensary, and its receipt be declared on oath, it is obligatory upon the grand jury to present a corresponding sum, or at least a sum proportionate to it. In the first case which is here supposed, the medical practitioner may or may not be a proper person; but any how it follows, that whatever may be the sum contributed from his own purse, or is above *boná fide* subscriptions, the county is assessed to the same amount, or nearly so, in violation of the statute. In the second case, it is probable the person so selected will be duly qualified; but whether competent or incompetent, in either case the formation of the institution may be unnecessary, from its proximity to a similar one: or again, even if necessary, there is no sufficient check to compel the medical officer to attend to his duty to the poor, especially when other than humane considerations have led to his appointment. Several instances are given in the course of these remarks, in which the relief of the sick poor seemed to be held of inferior moment; and others, again, in which it was grossly neglected. For these reasons it would seem that the principle is objectionable which makes the presentment *necessarily* consequent upon a certain sum being subscribed, as well as, in the first instance, to depend entirely upon it. With or without subscription, it should be granted if required, and only in such cases as required; and the power of subscribers to establish Dispensaries should be restricted. The next point for our consideration is the *amount* of the sum to be presented.

The ambiguous expression used in the act (45 Geo. III.) "that *it shall be lawful* for the grand jury to present a sum equal to the amount of private subscriptions," has led to a different practice under the law in different counties. In Roscommon it was the custom to present a sum equal to that subscribed. In Cork and Kerry the presentment was to a less amount. The grand juries had here availed themselves of a late construction put upon the act, which declared the sum presentable to be at their discretion. But the deviation from the ordinary practice of granting pound for pound, in proportion to the money subscribed, was much complained of. It was felt as an encroachment upon the funds, which, in their low state, they were little able to bear; and great dissatisfaction was expressed that the grand juries should cease to fulfil what has hitherto been presumed to have been the intention of the legislature, because it was now decided not to be binding upon them according to the strict letter of the law. This reluctance on the part of the grand juries to present, as they were wont to do, arose from the heavy expense which had been entailed by the system upon the counties. It had the effect, however, of raising an objection to subscribe, in the minds of many; for it had become quite a matter of uncertainty of what amount the county grant would be, and which might, after all, depend more upon the degree of influence which the superintendent officers happened to possess with the grand jurors, than the sum actually subscribed.

Thus the subscriptions falling off, and the presentments being curtailed at the same time, the resources of the Dispensaries had so materially declined that their existence was, in some places, brought into great jeopardy. In one or two instances, on the contrary, the reduction of the presentment was to be approved of. There were ample funds belonging to the charity, which were allowed to accumulate from year to year, while its immediate wants remained unprovided for. This was the case at Killarney; and here the permission given to the grand jury, of presenting at their discretion, or even withholding the presentment, was very properly taken advantage of. Hence it is clear they ought not to be called upon to assess a sum in all cases equal to the subscriptions certified, but only such a sum as may be equal to the necessity of the

case. A *supplemental* assessment, however, should always be made compulsory; such as would be sufficient to meet the existing exigencies of the institution. If the subscriptions decline, the presentment should be increased, and *vice versa;* by which plan, the funds would always be kept to a certain amount, not carried beyond, nor sinking below, what is deemed necessary for effectually providing for the relief of the sick poor.

If it be objected, that this mode of supplying the deficiency of subscriptions by assessment will have a tendency to diminish, or even to extinguish, private charity, it should be borne in mind, that although every encouragement is given to the present plan, it is attended with very imperfect success. Indeed, the low amount of subscriptions is scarcely worth considering, when the selfish stipulations are taken into account with which the contributions are too often accompanied. The privilege of being an administrator of the affairs of the charity—of having, in return, a vote and a right to issue visiting tickets—would still be continued under the proposed plan, as an inducement to persons to subscribe, while the unfeeling would be forced to contribute, and the expense not fall upon the benevolent alone. But it may be asked, upon whom should the assessment be levied? Not upon the struggling shopkeeper, or the occupying tenant, who barely exists after paying a rent which absorbs all his profits; not upon those who are but one degree removed above the lower classes, and, in too many instances, no better off than paupers themselves. Any increase of the county grant, under the existing circumstances, would only add to the general embarrassment—would only, in fact, impose a fresh burden upon the poor. But the evil would be in a great measure corrected, if the taxation were borne by the landlord; payable, however, in the first instance, by the tenant. To whatever amount the occupier of the soil might be assessed, it should be taken in lieu of so much rent paid to the proprietor; or the money required for the support of the medical institutions might be supplied from a general rate.

The entire management of the Dispensaries rests with the subscribers. They make by-laws, elect medical superintendent and committee, appoint treasurer, &c.; and as they are unrestricted by the law, and independent of the control of the grand jury in several important matters connected with the establishment and practical operation of the Dispensaries, they differ widely in their mode of conducting them. The principal differences have been explained in detail, and various inconsistencies and irregularities noticed, under the respective heads into which the subject has been divided; and hence it may be gathered how much more it would be for the advantage of the public, if, instead of being left to the arbitrary direction of the subscribers, an uniform plan of management were established in every instance.

But to whom can the administration of the affairs of a charity be so well entrusted as to those who chiefly contribute to its support? With whom can there be so strong a motive, as with those who have raised the funds, to take care that they are economically and legitimately applied? They are, besides, best fitted, by their local knowledge, to undertake the trust; and if it were withdrawn from them, it is to be feared they would cease to subscribe. On such grounds it would be advisable, without doubt, to leave the management entirely in the hands of the subscribers, provided it were really found that they ably conducted it; but the fact is otherwise. Of course I state the general impression made upon my mind by the result of my inquiry, and the experience I gained in those parts of the country which I visited. The particular instances which I met with of well-regulated institutions, should rather be adduced to the credit of the individual managers and medical officers themselves, than in favour of the system usually adopted. The only security, under the existing law, for the proper management of a Dispensary, is to be found in the combination of gentlemen who subscribe to it. But they are in general content with paying their money, and do not consider that they are bound to do more. They seldom visit the institution, or take part personally in the regulation of its affairs. Even the committee they elect is merely nominal: no minutes kept of their proceedings, no meetings held, but every thing left to the medical officer and to the treasurer, who is probably his friend: and it is not to be expected that, in such a case, without the corrective influence of an active and intelligent superintendence on the one side, and a sense of responsibility on the other, the charity to which they belong should fulfil its legitimate ends. One or other of the following evils is liable to arise: either a falling off in the activity of the charity, or a totally inert and inefficient state; an irregular performance of duty, or even palpable neglect; a growing or complete indifference to the wants of the poor; a waste of the funds, or an undue diversion of them, and relief improperly bestowed. Lastly, instances of peculation and jobbing with the funds may be added to these and other abuses which I have had occasion to notice in the course of my remarks.

Thus, in May 1833, the Treasurer of the Charelville Dispensary died in debt above 300*l.* to the charity. He had returned to the Committee, *as paid*, the druggists' bills, the salaries of the surgeon and apothecary, and other items, which all remained due at the time of his decease. The funds of the Cork General Dispensary had also been considerably embarrassed by a defalcation to the amount of 700*l.* and upwards, on the part of the late Treasurer, who, it should be observed, was still kept as accountant to the Dispensary, at a salary of 20*l.* per ann. To meet the deficiency, he had given up a deed secured upon house property, and producing 50*l.* per ann., to be held by the institution till the debt he had incurred should be paid off; but no interest is accruing to the funds of the charity, and it became necessary, in consequence of their low state, to apply a legacy of 500*l.* to the liquidation of unpaid debts, the interest of which is lost also*. It is clear, however, from the cases of flagrant abuse just given, that some better regulations are required in respect to the office of treasurer. Either he should be obliged to give security, or the money, instead of being left at his entire disposal, should be deposited in the Savings' Bank, but not in the name of the treasurer only.

By making the law precise, in the several particulars to which I have alluded, the enormities and abuses incidental to the present system, and the defects arising out of its imperfect organization, would in a great measure be obviated. Still, some expedient is required beyond an alteration of the law—some amendment in the mode of conducting the Dispensaries, so that their actual management may be in strict conformity with the law. With this view, I would suggest that clergymen of every denomination should be associated with the subscribers in the administration of the affairs of the charities, and that they and the treasurer, in virtue of his office, whether they subscribe or not, belong to the committee. By putting such persons in the direction, and in full possession of such privileges as the subscribers enjoy, they would feel that a certain responsibility attached to them, which would ensure their attending regularly at the meetings, and duly discharging the duties which were committed to them. As a further check against mismanagement, the plan has been suggested, and partly acted upon in the county of Cork, of appointing a board of superintendence from among the grand jury. They would represent the interests of the landed proprietors, upon whom it has been proposed to levy the rate, and who ought to have the power of protecting themselves against any misapplication or useless expenditure of the funds, by a strict "surveillance" over the charity. Such a board is appointed for the superintendence of gaols, and might be extended to the medical institutions. Its object would be to audit and certify the accounts, examine the reports, and inspect the establishment: not, however, to interfere with the internal management, so much as to exercise a controlling power over it. But, besides visiting the charities themselves, the grand jurors should appoint a medical inspector. This they already do for the gaols; and, at all events, a medical man is best fitted, whether it be for the inspection of the gaols or the medical institutions; and he could undertake the duties of both offices at the same or a small additional salary.

There is still another expedient to which I must direct attention before I conclude this part of my subject. I mean the annexation of a ward, with a few beds, to certain Dispensaries.

It is objected, that this appurtenance, or appendage, would tend to a permanent heavy increase of expense; the beds being always filled, or nominally so, with one or other description of patients: but it should be considered whether the advantages resulting from such a plan would not be more than commensurate with the expense attending it. A great deal of the distress among the poorer classes is, beyond a doubt, to be ascribed to the inadequacy of medical relief, and especially to the want of hospital accommodation The second part of my report will embrace this division of the subject. But it may be here remarked, that painful instances were stated, in the course of my inquiry, to have occurred of late, in which persons seized with fever, or cholera, or to whom an accident had befallen, were obliged to be abandoned to their fate—left under a hedge, or in a ditch or pit, by the road-side, to perish—because there was no place to take them to. If a wandering beggar was taken sick, he had no alternative, in several places, but to lie in the open air. Sometimes the poor would build a hut over him. This had been done in the case of a wretched object whom I found by the road-side, between Portumna and Eyrecourt, in the county of Galway. A man seized with the cholera, at Bantry, after lying all day in a boat, was put into a store, where he died. A woman, attacked by the same disease, had expired in a ditch. At Kenmore similar instances were adduced. Also, in the evidence upon the Athlone Dispensary (Westmeath side), the case is mentioned of some unfortunate persons

* For further proof of abuse in the fiscal management, see account of the North Cork Charitable Infirmary, in the second part of my report.

being ill with fever, who were turned out of their lodgings, and could find no shelter. Two of them died. Besides this sacrifice of life, there are other evils resulting from this exclusion. It tends much to the extension of pauperism. The external assistance at present afforded by the Dispensary does not relieve the poor man from the expense attending sickness: his capital is consumed in procuring drinks, sustenance, and other necessaries, to alleviate the sufferings of the sick bed; his clothes and furniture are pledged, to supply his wants in the course of a protracted illness; and when, at length, he recovers, he finds himself and his family beggared.

However, to avoid expense, it is not proposed to annex more than from five to ten beds to a Dispensary, and only in those medical stations where the distance from the County Infirmary, or Hospital, is so great that, although taxed for its support, the inhabitants of the district cannot have recourse to it. To give an idea of the permanent expense of such an establishment, beyond the first outlay for fitting up, furnishing, &c. it may be stated that each bed, if constantly occupied throughout the year, would cost about fifteen pounds, taking one case with another; which would include the maintenance of the patient, with medicines and nurse-tenders. There need be no additional expense for medical attendance.

[To be continued.]

ON CANCER, AND NOLI ME TANGERE.

By Alexander Ure, M.D. M R.C.S.
Late House-Surgeon to the Royal Infirmary at Glasgow.

In the following observations I intend to confine myself principally to the consideration of a mode of treating carcinomatous affections, recently introduced into practice, and to supply a rationale of its action, which I believe to possess some novelty.

In the infancy of the healing art, its professors, like the astronomers, sought to illustrate their own pursuit, by giving names to objects, derived from fantastic analogies. Thus the word cancer, signifying a crab, was introduced into pathology to denote first of all a tumor in the breast, surrounded with large veins, which may be said to correspond, in some measure, to the claws of a crab. "Struck with this resemblance," says Cayol, in the proem to his Treatise on Cancer, "the Greeks gave to the tumor in question the name of *καρκινος*, synonymous with the Latin word cancer: it may be, that they wished to express thereby the impression which one feels at the sight of this loathsome malady, in bestowing upon it the name of an animal, the aspect of which is to many people offensive."

In the progress of time, as other affections came to be recognized which seemed to resemble cancer of the breast in some of their symptoms, or in their horrible effects on the animal economy, though differing in form and situation, they were equally designated by the appellation of *καρκινος*, cancer, from which *καρκινομα*, carcinoma, the term now commonly received, is deduced.

If the researches of modern pathologists have been unable to draw aside the veil which hides the nature of a disease that has baffled all the efforts of the healing art, they have, however, reduced to their anatomical elements, changes of structure so singular and complicated as seemed to have defied description. These tumors have thus been proved to be ultimately reducible to two adventitious morbid tissues—each possessed of a peculiar structure—each presenting uniformly the same texture, whatever be the part of the body in which it is developed. They are, the scirrhus or hard cancer, and the fungus or soft cancer. The latter offers three modifications*.

1. Medullary fungus, with predominance of the encephaloid tissue.

2. Fungus melanodes, with black discolouration, from the excessive deposition of the colouring matter of the blood.

3. Fungus hæmatodes, with the prevalence of the thickened and dilated veins over the encephaloid tissue.

These two, then, are the grand types; we always find one or other of them present, sometimes both, in every cancerous tumor, whatever be its seat.

Wherever they occur they must be regarded with solicitude, as being either the precursors of a constitutional affection, which must lead to their multiplication and increase, or as being the outward visible sign of an inward deeply-rooted and incurable disease.

* Dr. R. Froriep in Encyclopädie der Medicin u. Chirurgie, Berlin, 1835.

When once established their march is destruction. The part primarily attacked first falls a prey, and then, step by step, each surrounding texture without any distinction. In this respect, Ovid has defined the disease with nosological precision.

Utque malum late solet immedicabile cancer
Serpere, et illæsas vitiatis addere partes.
M. II. 825.

Every part of the animal frame, from the most simple, nay, almost inorganic tissues, to the most complex organs, have in their turn yielded to the ravages of cancer.

Those writers who have instituted a comparison between the effects of this disease and gangrene, have egregiously erred. For, as an eminent author* has observed, gangrene seizes suddenly the part it is about to destroy, which soon thereafter is circumscribed by a well-marked line, beyond which it may not pass, whereas the cancer steals into the sound tissues by imperceptible degrees; in its manner of attack it is a sort of corrosion, which advances indefinitely.

Gangrene kills the part, and then abandons it to the external agents of dissolution; on the contrary, cancer consumes, devours, parts still endowed with life. Hence the ancients depicted it as a ferocious animal which gloats over its prey, and leaves it not till all be devoured. They have even carried this idea so far as to have recommended that the cancer should have daily supplies of meat presented to it to allay its hunger, and appease its fury.

A constant character of this class of maladies—one which never fails—is that, left to themselves, they are not susceptible of cure. They may, no doubt, remain stationary for a certain length of time, and even during the natural life of the subject. But when a change is wrought in their condition, their tendency is ever to augment, never to diminish. Lastly, arrived at a certain pitch, they occasion various aberrations of function, especially of nutrition; whence result the emaciation, loss of appetite, the dirty yellow or leaden tinge of the complexion, the hectic fever, and other signs of cancerous cachexy. Death is the only means of emancipating the unhappy sufferer from the accumulated load of misery.

It would be a waste of time to enter upon an enumeration of the different hypotheses that have been promulgated as to the nature of cancer; suffice it to say, they are vague and absurd. An avowal of ignorance is better than vainly speculating about the cause of a disease which has eluded the sagacity of every inquirer in every age.

To the advanced state of organic chemistry we are indebted for our only minute knowledge of the constituent parts of cancerous tumors. Probably at no distant period, when we become still more intimately acquainted with these products of unhealthy action, we shall be enabled, by a synthetic mode of induction, to arrive at the true explanation of their origin. In the following elaborate analysis of M. Foy *—

	Fung. Medullar.	Scirrhus.
Albumen	47·00	42·00
White fatty matter	7·50	5·00
Red ditto	5·35	3·25
Osmazome	4·00	0
Fibrin	6 50	5·85
Water	8·00	5·00
Oxide of iron	1·35	1·65
Subphosphate of lime	6·30	16 60
Carbonate of soda	2·75	5·00
——— lime	4·00	6·60
——— magnesia	1·00	0·85
Muriate of potash	2·70	4·10
——— soda	2·00	3·25
Tartrate of soda	·35	0 85

it will be seen that in scirrhus and encephaloid, albumen is the principal component. That this is not healthy albumen may be fairly presumed; but wherein consists that modification in its nature which constitutes the morbid deviation, has not been ascertained. The cause which determines the deposition of this morbid albumen is alike involved in obscurity; consequently we are left in the dark, destitute of the means of counteracting its baneful effects on the system at large.

It is generally admitted that the only way to get rid of an incurable disorder is to take away from the body the affected part, provided that be possible. Hence from time immemorial the external treatment of cancer has consisted in its removal by the knife, ligature, or caustics. As the caustics hitherto employed have been for the most part inefficient, owing either to the difficulties encountered in applying them, or be-

* Monsieur Cayol.

* Archives générales de Médecine, tom. xvii.

cause they did not penetrate to the roots of the disease, they are but seldom resorted to. Indeed, the only remedies of this class that continue in use are arsenic and corrosive sublimate. But the action of both requires to be limited to a very small extent of surface, from the danger with which their absorption into the system is fraught. Hence in the great majority of cases, surgeons consider the knife as both the readiest and safest plan for adoption. But that method is not without its inconveniences. It is undeniable that the operation, say for cancer of the breast, is neither very difficult, nor perhaps very dangerous. The wound inflicted by the scalpel differs in no wise from a simple wound—it cicatrizes for the most part speedily; but what is the sequel? After a few months have elapsed, it may perchance be a year or two, the disease breaks out afresh in the cicatrix, or in some other part of the body, and that with increased virulence. Thus, independently of the natural repugnance evinced by females against all such operations, and the perils they may induce, we find superadded the frequency of relapse. It cannot be denied that there are exceptions, where the patient has survived many years the operation, but such, alas! are comparatively rare.

In a paper published in the MEDICAL GAZETTE of December last, I described the chemical and therapeutical properties of an escharotic, which has been successfully employed in the treatment of scirrhus and carcinoma, by Dr. Canquoin, of Paris. It is a curious fact, which appears to have been overlooked, that our illustrious chemical philosopher, Sir H. Davy, was the first to point out the corrosive nature of the chloride of zinc, the caustic in question. He says, p. 376 of his Elements*, in reference to the compound procured when zinc is burned in chlorine, "Its taste is intensely acrid, and it corrodes the skin."

In the above paper it was shewn that chloride of zinc has a very powerful affinity for albumen. Now I have no doubt, that a part of its efficacy in eradicating from their ultimate ramifications cancerous tumors, is to be ascribed in no small degree to the powerful action it exercises on albumen. In this way numerous minute points, undiscoverable by the surgeon, and inaccessible to his knife, are searched out and destroyed. For when the chloride of zinc, whether the formula of the flour paste of Canquoin, or in that of the sulphate of lime paste*, as proposed by myself, comes into contact with the morbid albumen, it gradually penetrates its substance so as to deprive it of vitality, and to form an eschar, whose thickness you can estimate beforehand with unerring precision.

It is one of the great truths of modern physiology, that the vital and chemical forces are antagonists to each other, and hence those parts in which the vitality is feeble are soonest affected by chemical agents. Thus we may conceive how the morbid albumen, prone to spontaneous changes, is more readily affected than the surrounding parts by the above phagedænic substance.

The operation of this caustic is purely local; rarely, except it be applied on the face near the eyelids, where there is much loose cellular tissue, does it give rise to any surrounding inflammation or intumescence. The eschar is separated in most cases from the 8th to the 12th day, coming away quite entire, and leaving behind a singularly healthy sore, which heals with great rapidity. Canquoin is of opinion that it modifies the subjacent tissues; it assuredly gives rise to healthy granulation and laudable pus. In the instances where I have applied it most largely, I have never known it productive of the slightest constitutional disturbance. The pulse remained natural, and the skin cool. The pain accompanying its action is of a violent burning character, persisting with great intensity for the first 7 or 8 hours: after that time, that is, when the surface is fairly eroded, it becomes supportable, as the patients tell you, and continues so during the remainder of the application of the remedy. An important point is, that the pain is in

* Elements of Chemical Philosophy. London, 1812.

* Chloride of zinc, in order that it may act with efficacy, must be made in a concentrated form. When diluted, it acts merely as an irritant. Being extremely deliquescent, it would become rapidly dilute, if some means were not taken to counteract that tendency. It is well known that sulphate of lime recently calcined attracts moisture with great avidity, consolidates it in its substance, and still remains dry. Hence, when such anhydrous gypsum is mixed with the chloride, it not only enables us to reduce its escharotic power to any desired standard, but it protects it from change, and by its porosity allows it gradually to transude from the body of the cake into the morbific tissue.

a great measure under the control of opium; a full dose, say from xxv. to xxxv. minims of the liquor opii sedativus, seldom fails to sooth the pain, and render the application very tolerable. I will not pretend to define the absolute amount of pain occasioned, since that greatly depends on individual peculiarities, but this I will tell you, that a lady on whose breast I recently applied a thick layer of the phagedenic paste over an area of a couple of square inches for three days continuously, had some time after an attack of urticaria, to which she was, in common with her family, subject; and she assured me, after her recovery, that she would sooner suffer ten such applications of the paste, than a single attack of nettlerash.

The cases to which the chloride of zinc is best adapted might with propriety be classed into subcutaneous and cutaneous cancers, and carcinomatous ulceration, frequently termed *noli me tangere.*

To the former belong scirrhous tumors, &c., developed in the conglomerate or conglobate glands, and in the free cellular tissue, where the use of the knife is impracticable, or the patient refuses to submit to extirpation by incision. To the second appertain those little lenticular or pisiform indurations which make their appearance in the skin. They are at first quite indolent, and often remain so for years. Mr. Guthrie shewed me lately a military man who had two of them upon his face, near the root of the nose; they had existed for 11 years, and occasioned little or no inconvenience. These indurations are apt, however, to become ultimately painful, and to terminate in ulceration. It is these little bodies which, when situated upon the face, I believe have been made to form a genus apart, and dignified with the title of *lupoïd tubercle*—a distinction quite superfluous, since they approach closely, as well in their symptoms as in their intimate structure, to the scirrhus of the mamma and other parts. When ulceration takes place, the ulcer is always central and round, covered with a little greenish crust or scab; it looks as if the middle had been punched out. There may be a primary affection, the *papula maligna* of the Germans, and the *lupoïd tubercle* of some modern nosologists. There may be also a secondary affection, in which case they appear most commonly in the vicinity of a cancer in the breast or rectum. They have also been observed about the skin of the neck, the abdomen, and the extremities. Cayol is of opinion that, generally speaking, these small cutaneous scirrhi are a sure criterion of the cancerous diathesis, and that they become, sooner or later, complicated with some other malignant affection.

So long as they exist alone, they never occasion much suffering, and when they ulcerate, which is not very frequent, they never acquire a great volume. In their course they are not to be compared with the primary cancerous ulcer. If these be productive of little uneasiness, and often unattended with constitutional derangement, let it be remembered that they are implanted in a part endowed with a low degree of sensibility.

I have been for some time past in the habit of seeing a lady affected with cancerous ulceration of the breast, in whom their rapidity of reproduction is remarkable.

In conclusion, the chloride of zinc paste may be most beneficially applied to carcinomatous ulceration, independent of scirrhous tumors. The ulcer commences in a desquamation of the skin, or excoriated pimple, and spreads insidiously in extent and profundity. The surface presents a rugose or scabrous appearance; the base and margins are hard,—the latter are elevated and thickened, not always everted; the surface emits a little sanies, and frequently bloody ichor; the confines are often varicose, and of a reddish or violet hue. It is sometimes free from pain; at another smarting pain is felt, or a pain resembling the punctures of needles. It is vulgarly denominated *noli me tangere;* but as such ulcers are incapable of spontaneous cure—as they often follow the same course as cancerous ulceration proceeding from another cause—as they often present, although to a less degree, various characters of cancer, such as the lancinating pain and the occasional hæmorrhages—as we often find the neighbouring glands diseased, and as they frequently coincide with other cancerous diseases—I see no reason for calling them by any other name than cancerous ulcer, as Cayol has done. I adduce the three following cases in illustration of the above principles, and of those laid down in my former papers.

Case I.—*Scirrhus of the Breast—Cure.*

Lydia Debeney, æt. 46, admitted into the Westminster Hospital, February 2, as a patient of Mr. Lynn*.

The following symptoms were observed at the time of her admission. Above and to the outer side of the nipple of the left mamma, a hard nodulated tumor, about as large as a hen's egg, is to be felt. The tumor appears to be perfectly isolated from the superincumbent integument, except at one point, where there is a distinct puckering in the skin, which is otherwise healthy; it is quite moveable, and unconnected with the surrounding tissues. The nipple is slightly retracted; a small indurated gland is to be felt in the axilla. Has frequently severe pricking and lancinating pain in the tumor.

She gives the following history of her case:—Three years ago, in nursing her child, she remembers that more than once it fell heavily on the left breast, causing rather severe pain, which, however, soon subsided. After this she now and then noticed a slight swelling in the breast, which gave her but little uneasiness. About six months prior to the date of her admission the tumor had attained the size of a walnut, and then, for the first time, was attended with pain. By the advice of a medical man she obtained admission into the hospital, in order to have the tumor removed.

By Mr. Guthrie's kind invitation, in concurrence with Mr. Lynn and his other colleagues, on February 9, I applied the phagedænic paste, consisting of one part of chloride of zinc to two parts of sulphate of lime, the scarf skin covering the tumor having been previously stripped by a blister. The paste occupied an oval space about $2\frac{3}{4}$ inches by two inches, and was three lines thick.

Feb. 10th. — Suffered considerable pain during the afternoon and evening, which prevented sleep. Pain is now much abated. Had forty minims of the liq. opii sed. in divided doses. Pulse natural; skin cool. There is no surrounding swelling or redness. Bowels slow.

Ordered a dose of castor oil.

* For the history of this case I am indebted to Mr. Thurnam, of the Westminster Hospital.

12th.—The pasty cake was removed. There is a slight intumescence of the breast, and an extremely narrow reddish areola bounding the eschar, which is dry, white, renitent, and well defined. Says she felt some pain this morning. Countenance good; pulse natural; tongue clean.

Apply warm poultices.

17th.—Eschar has come away; it is about $2\frac{1}{2}$ inches by 2 inches in size, and half an inch thick at the centre. Its under surface is rendered uneven by striæ running in a radiated manner towards the middle, resembling in some degree a large mushroom. There is little or no surrounding inflammation. Functions natural.

20th.—On carefully examining the bottom of the sore, a small granular indurated substance was to be felt, for which a thin layer of the paste was re-applied. From this the eschar separated in a few days, leaving a singularly healthy sore, free from any hardness, which rapidly cicatrized, and she was dismissed cured about the end of March. The indurated axillary gland disappeared in the course of the cure.

Case II.—*Noli me Tangere, or Cancerous Ulcer of the Face—Cure.*

Anne M'Gullen, æt. 71, married, and the mother of several children. Below the inner angle of right eye is situated an ulcer, possessing the characters of the carcinomatous ulcer. The caruncula lachrymalis, punctum, and semilunar fold, are involved in the malignant degeneration.

About a year ago she states, that, after an attack of erysipelas, a sore made its appearance at the outer angle of the eye; this healed up, but soon after was followed by the present sore, which has continued to get worse ever since. Has no pain in the ulcer. On the cheek, about three lines from the margin of the sore, is a small lenticular induration of the skin, with a minute central point of ulceration.

Her general health is tolerably good. By the kind permission of Mr. Walker, under whose care she was a patient at St. George's Hospital, I applied to the surface of the sore a thin layer of the phagedænic paste. The eschar came away about ten days after, leaving a healthy sore, which has since healed.

The escharotic was not permitted to touch the diseased caruncula, for fear of exciting ophthalmic inflammation; that, therefore, remained to be snipped away after the ulcer was cured.

CASE III.—*Noli me Tangere, or Cancerous Ulcer of the Face—Cure.*

Elizabeth Rawlinson, æt. 40, married, a patient of Mr. Lawrence, in St. Bartholomew's Hospital. On left cheek is a narrow strip of ulceration, running along the lower margin of the orbit, and extending a little way up its outer margin. The edges of the sore are hard and prominent, and the surface in some points is covered with a little greenish crust; surrounding integuments are healthy, with the exception of a little indurated spot in the skin, below the inner angle of eye. The sore is free from pain. States that five years ago a splinter of wood entered her cheek, close below the orbit, which produced a little hard spot. This remained unchanged till the month of May last year, when she accidentally struck her face against a door, and from that circumstance she dates the commencement of the ulceration, which, notwithstanding a variety of treatment, has been creeping along insidiously ever since. Her general health is good.

Mr. Lawrence considering it a proper case for a trial of the chloride paste, was good enough to allow me to apply it on the 25th March. On the 30th the eschar came away, leaving a well-defined healthy-looking sore. Soon thereafter she became an out-patient of the hospital, and on the 13th April returned, and shewed herself perfectly cured.

13, Charlotte-Street, Bedford-Sq.
May 17, 1836.

DEATH OF A VERY AGED FEMALE.

EXAMINATION OF HER BODY; WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case, imperfect as it is, worthy a place in the Gazette, I shall feel obliged by its insertion.—I remain, sir,

Your obedient servant,
T. OGIER WARD,
M.D. Oxon.

Birmingham, May 17th, 1836.

A. B., æt. 96, cabinet locksmith, of very regular and temperate habits, had never suffered a day's illness till the last four years of her life, when she had a paralytic attack that deprived her of the use of her right side for sixteen weeks, and compelled her to relinquish her occupation, which she had continued for eighty-four years without intermission. While confined to bed with paralysis, a spreading ulcer of her leg from a blow healed up entirely; and at the end of the sixteen weeks she could walk about, which she continued to do till September last, when she fell down stairs, and from that time never left her bed, except to be carried to the night-chair. Nevertheless, she always said that she was not hurt by the fall, though her right side was quite paralyzed, and maintained perfect health, except a slight cough latterly during the night, to the day of her death. Her senses were acute, and her intellect clear, till within the last few days, when it became rather dull, and her speech indistinct. Her bowels also were less regular, and only acted on alternate days. Five days before death her daughter perceived a sore on the sacrum, of which she was not at all aware from any pain or uneasiness. The morning she died she ate her breakfast as usual, and was quite well at eleven; but in an hour afterwards she was found dead.

Sectio Cadaveris, 30 hours after death.—Body much emaciated, features remarkably calm; limbs rather stiff; hair thin, but not at all grey. Eyes particularly sunken, and cornea rather opaque. Only one tooth, the left upper incisor. Sore on sacrum; no ecchymosis on the lower parts of the body. Chest round, flattened laterally, muscles wasted and soft, cartilages not ossified, but the ribs were remarkably thin. The lungs were collapsed; the right was adherent to the pleura. Both were emphysematous in front, but the whole of the back and lower parts, especially the latter, was infiltrated with an almost fluid blood, that ran out when they were

cut, mingled with much serum and froth. These congested portions were still crepitant, but so friable as to break down into a pulp by slight pressure through the pleura, particularly in the lower lobes, and much resembled that congested and œdematous state of the lungs which is observed around gangrenous portions, but in this case there was not the slightest gangrenous odour. A small piece of the left lung was in a state of "grey carnification," being void of crepitation, and tough and leathery. Bronchi slightly redder than natural. The heart contained some fibrinous clots, chiefly in its right cavities; was small and very flaccid, and so soft that the finger passed with ease through its walls. Its proportions were normal, and its valves all healthy. One of the corpora sesamoidea of the aorta was enlarged and cartilaginous. The aorta was rather dilated at its arch, but there was no ossific deposit along its whole course to its division into the two iliacs, where the projecting angle was ossified. Its lining membrane was of the natural colour.

The liver was small, and the left lobe was fissured at its lower angle, horizontally, as if by the pressure of a string. There was a small lobe, like the lobulus Spigelii, attached to the front and lower edge of the right lobe. The substance of the liver was apparently healthy, but remarkably soft, and much congested. The gall-bladder contained some green viscid bile; the spleen was of the natural size, wrinkled internally, and softened like the lungs and liver, but of a brighter colour. The kidneys, deeply fissured, were small and healthy, but flaccid. The stomach was large, and contained some curdy mucus, probably the remains of the breakfast, but it was perfectly healthy throughout, although it was marbled with ramiform injection. The intestines appeared quite healthy externally, and contained some hardish fæcal matter. The os tincæ was rather wide (she had borne eight children), and there was an ecchymosed spot at the fundus, the size of a shilling. The ovaries contained a few serous cysts. The intervertebral substance was removed from above and below the sixth dorsal vertebra in front, but there was not the least approach to luxation, although the vertebræ appeared separated in front to the extent of half an inch.

Remarks.—The absence of decided appearances of disease in this case corresponds exactly with the permanent good health of the subject; for the adhesion of the pleura is so frequently found where there has been no reason to anticipate its existence during life, that it hardly deserves notice as a morbid appearance. The almost perfect freedom from ossific deposits is also another remarkable feature of this case. Was this connected at all with the temperate habits of the deceased? The death of the patient appears to have originated in the ganglionic system of nerves, which, no longer stimulating the flaccid and softened heart, produced congestion and imperfect arterialization of the blood in the lungs, an insufficient supply of the vital fluid to maintain the energies of the brain (indicated by the increasing obtuseness of intellect before death, together with impaired digestion and retarded peristaltic action of the intestines), and stagnation in the large venous trunks and in the liver. Although the brain was not examined, the extremely congested state of the lungs and liver, with the slight cough, and absence of signs or symptoms of suffocation or of bronchial disease, indicate that the lungs were gradually oppressed, but not overwhelmed, by the sanguineous accumulation; and preclude our taking the brain as our *point de départ* in investigating the series of morbid actions. The softened state of the tissue of the lungs, and particularly of the liver, is probably referrible to that tendency in stagnant or effused blood (observed in polypi of the heart and in the pneumonia of new-born children) to pass through those changes which are usually the results of inflammation, as coagulation, suppuration, &c.; in which process the containing or infiltrated organ, as the case may be, becomes implicated, and participates. This view of the cause of the morbid appearance is supported by the fact, that the patient lay constantly upon her back for a long time previous to her death. The unimpaired state of the digestive organs corresponded with the keenness of her appetite even to the last; for when her daughter, who gave her the last meal, perceiving that she rattled in her throat a little, ceased to feed her, and was removing the cup, she stretched out her hand, and would not part with it till it was empty.

REMUNERATION

FOR

PRACTITIONERS CONSULTED BY INSURANCE COMPANIES.

To the Editor of the Medical Gazette.

Sir,

More than six weeks have elapsed since the last number of the Medico-Chirurgical Review has been published, yet, hitherto, no notice seems to have been taken of the article on Insurances, though few could be more derogatory to the honour and dignity of the medical profession. That a sordid actuary, influenced by paltry notions of false economy, should utter an abusive tirade against the members of a too liberal profession, may not prove a source of much astonishment, though, *en passant*, it might be esteemed a matter of some surprise and doubt, if "one of the ablest actuaries in Europe" could not at once detect so gross and barefaced an attempt at imposition on the part of the medical profession, as that, which, it has been fancied, might be practised against the innocent and simple-minded Insurance Companies; but that a member of our profession, and the editor of a respectable journal, should permit his work to be made a vehicle for the propagation of scandal against the body of which he is a member, may well be deemed a sufficient cause of surprise and regret.

But to come at once to the subject matter in question, in the investigation of which the party referred to displays equally good taste and acumen, it appears to me, that the subject of medical remuneration by Insurance Companies ought not to be taken as one question, as it generally is, but should be divided into a series of minor ones:—as, 1st, are medical men justly entitled to seek remuneration for professional opinions? 2d, Are the opinions of medical men, when given to Insurance Companies, to be considered as professional, and where are the proofs to be found? 3d, Is either of the contracting parties more interested than the other in the effecting of an insurance? And, lastly, granting that *both* are equally interested, which of the two ought the medical man select to pay him his fee, and for what reasons? To the first there can be decidedly but one answer; yes, undoubtedly! For, to view the matter as a commercial transaction—and in this way it is most likely to come home to the minds of those most interested in opposing it—the medical man has embarked a large capital in his professional education, in return for which he receives nothing but the capability of forming an opinion, and that opinion, therefore, becomes as much an article of fair and open commerce, as a bale of cloth to a mercer, or a policy to an insurance office; and, if discovered to be incorrect, exposes the vendor to as much disgrace and loss, as the cloth, if damaged, or a dishonoured policy would bring upon the latter; and as no one would ask either of those commercial characters for a part of their merchandise without paying for it its due value, neither are they justified in seeking from a medical man what they would not grant to others. In reply to the second question, I would merely refer to the list of printed queries sent from the different insurance offices; and then ask, could any but a medical man fill them up? And if so, why must *always* one of the referees be a member of the medical profession?

The next question seems to me to be that on which the advocates of medical remuneration have generally failed; and this because they do not take, in the first instance, a sufficiently commanding position, by asserting, that in proportion as the company and the insurer are benefited by the opinion of the referee, in the same ratio are both of them justly subject to the claims of the medical man; the insurance offices having with great plausibility asserted, that as they are not the persons benefited, they ought not to be called on to pay the expenses. In reply to this I would observe, that they are commercial bodies banded together for their own emolument; for which emolument they are dependent on a certain class of customers, and, in order to obtain it with some degree of security to themselves, they are necessitated to employ an agent, whom they must pay, and a medical referee, whom some of them, if they can avoid it, will not pay: in this particular differing from the recruiting service, who might with as much justice tell the medical man, "it is not we that are to pay you for your trouble, but those whom you report upon; as, they being volunteers, it is upon them

the favour has been conferred." Though the reverse is the case; for while, to both these bodies, the obtaining a healthy recruit is a source of considerable advantage, the avoiding an unsound one is a matter of almost equal congratulation; but not so to the person desirous of being enrolled, who, feeling that his rejection is owing to the report of the examiner, let the matter be blindfolded as it may, is not likely to entertain a very friendly disposition towards him.

And now with respect to the last question, as to whom the medical man should take his fee from. From the Insurance Company, certainly; for their sakes as well as from respect to his own feelings; for though, as a matter of pecuniary emolument, it can be of little consequence to him through whose hands he receives his fee, it should always be borne in mind, that when the referee is the regular attendant of the insurer, it is almost more than can be expected that the former should completely forget the friendly relations which have existed between him and the person referring to him; the natural result of which must be the giving his mind a bias in favour of the latter and to the prejudice of the company. Impressed with this conviction, scrupulous persons will decline accepting a fee from the individual, while they can have no hesitation in receiving it from the company; and, in fact, the very offer emanating from the latter must at once bring to the mind of the referee the recollection, that on the present occasion he is called on, not to act the part of a friend, but strictly and impartially to discharge certain professional duties towards both, and to give an opinion which is recorded against him, and which, if not critically correct, may hereafter be adduced to the injury of his professional character.

So thoroughly are a few of the Insurance Offices now impressed with the conviction of this fact, that they always take care to have a referee of their own in every town in which there is an agent; while very recently another office, "The Sun," has adopted the plan of making each person applying to be insured deposit one pound in the hands of the agent, as the fee for the referee. Which of these modes is the more desirable to be generally adopted, is a matter of little consideration to the profession as a body, or to the undersigned as an individual; but that medical men may not sacrifice to a set of rich mendicants any portion of their hardly earned pittances, through a too refined sense of liberality — a liberality, by the by, which is not *permitted* in either the Premier or the Chancellor — is the earnest hope of

Your obedient servant,

OCEANICUS.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Observations on the Medical and Surgical Agency of the Air-pump. Read before the British Association, in 1835. BY SIR JAMES MURRAY, M.D. T.C.D. &c.

THIS pamphlet contains a variety of detached and somewhat desultory observations on the effects—first of rarefaction, and secondly, of condensation of the air over greater or smaller portions of the body.

The production of rarefaction on the surface, or a diminution of the atmospheric pressure, is represented as leading to various important curative effects; among others, that of increasing cutaneous transpiration, and carrying off "a great quantity of carbon and hydrogen from the circulatory system." By this contrivance it is thought that the disadvantages of stimulating, and of nauseating diaphoretics, may both be avoided in fevers and analogous ailments. In inflammations a still more important end, we are told, may be accomplished; for, "after full and free bleeding, it is often a question whether more blood can be lost with safety: here, its abstraction from the *diseased viscus*, and its diffusion among the sound vessels of the skin, unloads the *part affected*, without dangerously debilitating the constitution. We draw off the blood from the oppressed organ, but we do not risk the patient's life by too much waste of that fluid which sustains it."

In nervous diseases also, (though it is allowed to be less conspicuous) the beneficial effect of rarefaction is spoken of as well marked, and frequently very

efficacious. The object is to fill the vessels of the part, and thus elicit heat, and stimulate circulation; and the effects of this kind of dry cupping are illustrated by two cases, which, however, we suspect the medical reader would think scarcely sufficient to prove what is intended. The method of effecting this rarefaction of the surface is thus described:—

"For the purpose of insulating a patient's body from the external air, a small oval bath, of tin, zinc, or copper, is employed; its lip is furnished with a groove to contain luting, for connecting the lid or cover.

"In this lid is an aperture to pass over the patient's head, and around this opening is fitted a margin of air-tight cloth, which applies itself so as to embrace the top of the chest and back of the neck. The patient sits upon a seat, easily varied to a regular height, and his head is unconfined, the body and limbs only being inclosed. When the bath is thus adjusted, it is to be partially rarefied, either by the condensation of a little hot air or steam, or by a few strokes of the suction-pump.

"When the air of the bath is exhausted, to the extent of two inches, upon the mercurial gauge, it indicates the removal of *one hundred and forty-four pounds* from every square foot of patient's surface, or one pound from every square inch.

"Rarefaction to this degree is the utmost at any time required, and does not injuriously interfere with those great hydraulic laws which modify either the general or pulmonary circulation. But, on the other hand, when the principle is applied *topically* to a part of the trunk, or to the limbs, as no interference with respiration can then occur, *two or three pounds* of pressure may be drawn from every square inch, but there is seldom occasion to proceed to that extent. To draw away even a fifteenth part of the atmospheric gravity, will, I think, be found a therapeutic agent, abundantly powerful for any useful purpose."

Scarcely less importance is attached to the effects of compression by condensation of the atmosphere; but the manner of accomplishing this, except in one or two instances, is not sufficiently explained. We are told, indeed, with regard to the reduction of a prolapsed uterus, that—

"This was effected simply by connecting the neck of a small oiled bladder with the air-syringe; when the air was forced into the bladder, it was reflected around the protruded uterus, embracing that organ, as if in a double night-cap; it then grasped, corrugated, and diminished the prolapsed womb, and propelled it back into the pelvis, pushed on, and retained in its place, by the expanded bladder."

And again:—

"When you put the hand into a wet bladder, and exhaust the air, there is a very intense degree of cold generated, and the compression is more than the fingers can easily bear. I heated the bladder in warm water, and even then the temperature of the hand was reduced. The fingers seen through the bladder, were wrinkled and bloodless. There is no doubt but that hæmorrhages would be instantly suppressed by this tight embracing *involucrum*, which adapts itself to every eminence and depression of the joints and fingers, so as to press equally on all parts. There is very brisk re-action when the compression is removed, the hand becomes red and hot, by the increased return of the circulation to the surface.

"Drawing a limb into a tube of oiled silk, or even a softened bladder, open at both ends, and confined by tape, above and below the part affected, presents a ready method of effecting speedy and equable compression. When the contained air is withdrawn from this envelope, it contracts and embraces every point, *high* or *low*, in an equal degree."

We have thus drawn attention to Sir James Murray's views, because they are undoubtedly ingenious, and to a certain, though, we think, limited, extent will probably be found to admit of useful application to practice.

An Introduction to Phrenology, in the form of question and answer. By Robert Macnish.

It must be allowed that the phrenologists cater much for the amusement of the public, however little they do for their edification. They produce manuals and vademecums in abundance, richly stored with anecdote and choice extract; but we must take by far the greater part of their pleasantries with a grain of salt, for we do not find them very scrupulous either about facts or vouchers.

The present little book is a lively per-

formance, characterized by most of the peculiarities of the author of the Anatomy of Drunkenness. "The form of question and answer," says Dr. Macnish, "has been adopted as well suited for a short sketch of a *debatable* subject like the present. It has enabled me to bring forward the objections to the science in the way in which they are usually stated, and to meet them with suitable replies."

The author, however, has not confined all his *debatable* matter to his text: some of it, and not the least diverting, is thrown into the notes. We have in this part some rare extracts from Cobbett, on Milton, and on the choice of a wife; also remarks on the accomplished artist who trains the *learned fleas*, &c. &c. The following passage we extract as containing a curious error:—

"Phrenologists positively declare, that no correct inference can be deduced in cases of old age and diseased brain; yet we had lately the skull of Dean Swift brought forward as an evidence against the science, in the face of the notorious fact, that the Dean died at the age of seventy-eight, had been subject to loss of memory, and frantic fits of passion, eleven years before his death, and that the last five years of his life were passed in idiocy."

Mr. Macnish makes an odd mistake in this matter. If he look again into the Phrenological Journal—which he so often quotes as a work of authority—he will find that he has made a very ridiculous blunder. The skull of Dean Swift happens to have been brought forward by the phrenologists themselves as an evidence *for* "the science." The absurdity of such a proceeding—involving as it did a base attack on the character of the eminent deceased, we exposed in this journal (Med. Gaz. vol. xvii. p. 115), and if we are not much mistaken, Mr. Macnish himself will now freely admit the absurdity of all such "inferences"—whether the gist of the argument be for or against "the science."

That Mr. Macnish is a wag, and not very whig-radically disposed, seems to be a fair inference from the following question and answer:—

"*You have already hinted at the distinction between Individuality and Eventuality. Illustrate this point by some other examples?*

"Individuality concerns itself with what exists, Eventuality with what happens. Substantive nouns express the objects of the former, active verbs of the latter. When I say that Lord John Russel is a *little man*, that the Duke of Wellington has a Roman nose, or that camels have humps upon their backs, it is Individuality which suggests these remarks: when, however, I observe that *after being challenged by Sir Robert Peel, Mr. O'Connell contrived to get himself arrested, and then made a vow in heaven never to fight duels;* that the Houses of Parliament were burned in consequence of overheating the flues; or that Earl Spencer *rears the fattest cattle in England*, then the observations are suggested by Eventuality."

MEDICAL GAZETTE.

Saturday, May 21, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

LIFE INSURANCE POLICY FEES.

The Glasgow faculty, we find, have taken a deliberate and decided step in regard to the propriety of remunerating medical men consulted by assurance companies. Our opinions on this subject are known. We have long since expressed ourselves in favour of the practitioner being paid for his services when applied to confidentially, and on so delicate a point; nor have we yet read or heard any thing to tempt us to change our mind.

The resolutions passed at Glasgow are as follows:—

"1st. That henceforward no list of queries regarding the health of any individual, forwarded by, or on account of, any Insurance Company, to any member of this body, shall be attended to, unless accompanied by a fee.

"2d. That they are only claiming their right, when they require a fee for answering such queries. To do so with proper care is often a matter of considerable trouble: and as the value to the insuring parties of an accurate his-

tory of the individual's health, constitution, and habits, by one long acquainted with these circumstances, must be immense, it seems obviously unjust that the family practitioner should be called on to furnish such a document without remuneration.

"3d. That it is unreasonable the medical referee should demand payment of his fee from the applicant for insurance. Such demand may be fairly objected to, on the ground, that it lies altogether with the Insurance Company to satisfy themselves regarding the state of the applicant's health—that the information required is altogether for their security and guidance—and that the premium ought to cover this as well as other expenses.

4th. That the Insurance Companies are justly liable in payment of the fee, not only for the above reasons, but more especially from the consideration that the reference in question is in all cases a confidential one, and not unfrequently the information given disappoints the wishes and expectations of the parties desiring insurance. The idea of Insurance Companies getting confidential or useful answers to such delicate and searching questions as are contained in these lists, not only regarding the individual in question, but his family and relatives, by putting open schedules [without a fee] into his hands, and telling him to get them filled up as he best can, appears to the Faculty to be so absurd, as not to admit of being entertained for a moment."

We wish the other medical corporations would imitate at least the zeal of the Faculty of Glasgow, in consulting the interests of the individual members belonging to them. Their resolutions, we see, are not deficient in strength; and they must be allowed to embrace all the disputable points connected with the subject, which they effectually place in a prominent point of view, so as to secure the just censure and indignation of the medical reader.

A correspondent, who signs himself "Oceanicus," in the present number, has also taken up the question. His arguments are shrewd, and he views the subject in a clear and rational light. The companies have no right to call upon the profession to give mature opinions without adequate remuneration; nor do we see how a fair comparison can be drawn between the information elicited from mere non-professional friends, and those of vital consequence sought to be procured from the *medical* attendant.

"Oceanicus" is severe upon our contemporary, the Medico-Chirurgical Review, for advocating the non-paying side of the question; but more particularly for insinuating the possibility of gross frauds being practised by medical men, if the paying system were adopted. We think our correspondent needlessly tart with our contemporary; a little plain discussion, with temper, is all the subject requires.

On looking into the article referred to by "Oceanicus," we perceive that, with the exception of the apprehended frauds that *might* take place, there is nothing urged by the editor, possessing, in any striking degree, either novelty or force. He begins by putting the *medical* friend on the same footing as any other casual friend—"say his solicitor." He next supposes the applicant who desires to be insured procuring, from each of these, certificates, first of his moral character and habits, and secondly of his state of health; and then he asks, ought the Insurance Company to pay for either or both of these documents, or ought the applicant himself?

Now we say, that whoever makes the request to have the necessary certificate, is bound in honour to requite the party applied to. But the difference is very great between the *solicitor* friend and the *medical.* The former is not asked for a testimonial in the way of his profession; if he were, he would know exactly what entry to make in his cost-book: whereas the other is expected to give a strictly professional opinion, which, in general,

cannot be formed without much mature thought, and much anxiety, arising out of the peculiar position in which he is placed between the company and his patient.

It is, however, not a fair statement of the case, to say that the certificate is always, or even usually, asked for by the party wishing to be insured. The application comes from the Insurance Company, who have in an indirect, and apparently very disinterested manner, wormed out the name of the medical friend. And how do they then generally proceed? They send their formula to be filled up: they caution us—they tell us, lest we should certify falsely, that our answer *will be filed:* and at the mildest, they intimate that our reply is to be considered *confidential*—meaning, of course, that we should consult their interest at least as much as that of our patient. Who, then, will seriously tell us that it is unreasonable to expect remuneration from such persons, consulting us for their own immediate interest, and often without the ordinary forms of courtesy?

It may, perhaps, be urged, that it is not reasonable to expect the directors to pay both their own medical officer, and the referee of the person to be insured. But if the information they seek be not worth a fee, they ought not to take the pains of applying for it. We presume, however, that we may fairly infer the contrary, from their importunity, and the selfish and eager spirit with which they seek to effect their purpose.

As to the possible frauds which the Editor thinks might be practised, if the companies were bound to pay the referees of applicants, and which he supposes to be a "fatal objection" to such an arrangement, we can only say, that we discern nothing either so very fatal or objectionable in the matter. Nobody will suppose that in such a case, the directors would be so simple as to accept *any* reference that might be tendered to them, or that they would not distinguish between the reputable, and the obscure or unauthorized, practitioner. There can be no difficulty in doing so. The three medical corporations, who license practitioners throughout the country, have their printed lists, which the directors can readily procure, and thus satisfy themselves respecting the trustworthiness of those to whom they apply, and send the proper fee. If they suffer themselves to be cheated by an unprincipled "Mr. A," or Mr. B." of whom there is no account in the regular lists, they act foolishly with their eyes open. That any trick of the kind suggested by our contemporary were likely to be attempted by a respectable and regularly licensed practitioner, is, we think, as little probable, as it is creditable to any member of the profession to believe in its possibility.

PAUPER MEDICAL CONTRACT SYSTEM.

CONDUCT OF CERTAIN INTERESTED PARTIES.

To the Editor of the Medical Gazette.

SIR,

I PERFECTLY agree with you respecting the distressing case of paupers, when you say that "a perseverance in the present order of things, prejudicial at once to the true interests of the state, and revolting to humanity, can only be attended with ruinous and fatal consequences." In this strong observation, applied to the contract system, I fully concur: but let us not do an injustice to the newly-constituted Board, or place *ourselves*, by-and-by, in the position of people who knew, or might have known, that the order of things which we now join in condemning, existed in its "revolting form" previously, and yet did not draw down our expressions of indignation, until an opportunity came of throwing upon others the blame that, properly, was due only to ourselves. For myself, I should be ashamed to be convicted of such an error, where I have, before my eyes, evidence sufficient to prevent it.

The following picture and history of

facts will be recognized by many of your readers, so that I do not think you will require me to give a "local habitation and a name."

The town in which I live is a parish containing 22,000 inhabitants. The number of paupers for the year 1834, was returned 3,015. Let us add to this the number of paupers belonging to other parishes, but attended to in this, and we shall find a heavy charge entrusted to *one* medical practitioner. Taking into account also the liberality with which the Overseers give 'doctors' tickets' to those who do not receive other relief, we may altogether estimate the annual number of *sick* paupers at something more than 1,500. In the year 1834, the surgeon contracted to take the parish for something less than 70*l*., but received altogether 100*l*. The following year, obeying the regularly descending progression, it was taken for 5*l*. This year the vestry, a *little* ashamed of this kind of Dutch auction, has very liberally made an advance upon the tender, and allowed the surgeon for physic, time, and skill, bestowed upon a number of paupers, equal to six of his Majesty's regiments, besides all strange paupers, and all out of our 22,000 who choose to get "doctors' tickets" from the Overseers, the all-sufficient sum of 50*l*.!!

Now as it would be easy to shew that the surgeon ought to have 1,500 patients, and as each patient should hardly have less than 1 shilling's worth of physic (averaging severe and trifling illnesses) the physic only ought to cost 75*l*. We might next proceed to the matter of time, only it would be a waste of our own, and shew that the surgeon's *day's* work, or nearly so, ought to be his attendance upon these profitable patients, who pay him there-for —what? *minus* 25*l*.

Whence originated this order of things "revolting to humanity," and what has maintained it up to the present day, and made every year from 1830 worse, and more "ruinous?" An unworthy competition;—and was there among the medical men no voice raised against its "fatal" tendency? One only. The person who now addresses you wrote a circular letter setting forth the evils of the farming system, and proposing the establishment of a Workhouse-Dispensary, to be attended gratuitously by a physician and surgeon, and by a paid medical officer, who should be so adequately remunerated for his services as to induce him to forego private practice, and devote himself to his public charge. What was the consequence? A meeting of the medical gentlemen; where, *although a unanimous vote of thanks was passed to the writer*, the contract system came off unconvicted of its now loudly proclaimed guilt.

The meeting sanctioned it, and it went on three years longer, until, in March last, the *same gentlemen* again met to condemn their own offspring, and propose another plan for attending upon the paupers, which, for reasons I would rather not express, I considered highly objectionable.

At this time, having had two years' acquaintance with the parish surgeon, and been in the constant habit of seeing patients with him, I had the opportunity of impressing my opinion upon that gentleman, that some further attendance upon the poor was desirable, and he fully concurred with me in opinion, that the appointment of a physician would be desirable. I therefore tendered my gratuitous services, on condition that the select vestry would officially appoint me as physician to the parish. I was informed by one of the overseers, that they had entered into my views, and, in consequence of such information, I visited the workhouse several times. In the meantime a new vestry was formed;—at a meeting of this body it was moved by a surgeon, who had lately been town doctor, and carried, &c. that Dr. ——'s services be accepted when the surgeon called for his assistance, but by *no means* otherwise; at the same time the surgeon was, I am told, taken to *task for undertaking an office to which he was not equal*. The result, and the object of this, was, of course, to prevent my visiting the workhouse, or taking any *cognizance* of the *condition* of the sick. I was forbidden to inquire out the cases that might be benefitted by my assistance, and, at the same time, the surgeon has been deterred from any longer calling for it, under the dread of being censured, and perhaps dismissed for incapacity.

Thus this select body, uninfluenced by the much censured commissioners, tender 50*l*. for physicking upwards of 3000 paupers; consequently, 25*l*., less than nothing, for taking care of them, and then considerately interfere to prevent these poor wretches from having any further advice than that which they had thus generously provided.

What is the inference from all this? I dare not draw it. But I do request of your readers, if such things exist where the new arrangements have not come into operation, or did before that time, not to act otherwise than as members of a *liberal* profession; to deal censure where it is due, to take *some* blame to ourselves, and not ungenerously, and (may I say it) disingenuously, to clamour against those who, after all, when they have done the worst, have only trodden in a beaten path.

I am, sir,
Your obedient servant,
JUSTITIA.

May 13, 1836.

ON A NEW MODE OF TREATING BURNS.

By Professor Velpeau.

M. Velpeau recognizes four degrees of burns: in the first there is simply rubefaction; in the second, vesication; in the third the rete mucosum and first layer of the true skin are involved; and in the fourth, a part or the whole thickness of the skin is converted into an eschar. If left to themselves, the first either terminates in resolution from the second to the eighth day; or changes into true erysipelas, or vesicates; the second rarely recovers in less than ten or twenty days, as the epidermis becomes detached and suppuration established; the third is followed by ulceration of the dermis, and the cure is delayed for a month or more; the slough is not detached from the fourth in less than ten or twenty days, nor is the ulcer healed under from two to six weeks. The merits of numerous remedies for burns are examined in relation to these degrees.

1. *Cold water.* This is useful only in the first degree, which it cures in three or four days.

2. *Methodical compression with a roller.*—This is still more useful in the first degree: in the second and third, the epidermis should be removed previously, the wound covered with linen in which numerous small holes have been cut, spread with cerate, and then covered with charpie. It then prevents erysipelas. In the same manner it is useful in the fourth degree.

3. *Cotton, or down of the typha.* These are useless in the first or fourth: employed early in the second and third degrees, they absorb all moisture, become dry, and a cicatrix forms beneath them, sometimes in a week or fortnight; but very often they form a crust, which does not prevent inflammation or suppuration manifesting themselves. It is a remedy of little value, except in some few situations or cases.

4. *The Solution of the Alkaline Chloride.* This acts much like cold water; but it also improves the state of the ulcerations. M. Velpeau has tried the chlorides of soda and lime in more than fifty cases, but thinks their value has been greatly exaggerated, and that they are merely good detersives.

5. *Saturnine Lotions.* These act in much the same way: they are more sedative and less exciting than chlorides.

6. *Linseed Poultices.* These are too much neglected: they calm irritation, remove the elevated epidermis, and diminish suppuration in young and sanguine habits: where they are not beneficial after a few days, their use should not be persevered in.

7. *Leeches.* These applied around eschars prevent or diminish inflammation and erysipelas.

8. *Liniment of equal parts of Oil and Lime-water.* This in superficial burns, particularly of the face, is very useful; the parts being anointed four or five times daily with a feather. No dressing is required: in five or six days large burns of the first, and some of the second degrees, have been cured by it.

9. *Strapping with Diachylon Plaster.* M. Velpeau originated this plan, and has pursued it with great success since 1832. It fulfils the same indications as compression, besides hastening greatly cicatrization. The first degree is constantly arrested by surrounding the burn in such a manner that the straps will remain seven or eight days, and without hindering the patient from performing his usual duties. In the second and third degree, the epidermis must be first removed, and the wound cleaned, and the strapping renewed every third, fourth, fifth, or sixth day: the cure almost constantly takes place from the fourth to the sixth day, in the second; and from the tenth, fifteenth, or twentieth, in the third degree. In the fourth degree it represses the surrounding inflammation; does not hinder the separation of the sloughs, and as they become detached it favours cicatrization. Each strap must be from three quarters to one inch in breadth, and long enough to make one turn and a half around the burned part; the first being placed an inch below, and the last an inch above it: they must overlap each other so that only one-third of each is exposed; they must be very evenly applied, so as to compress equally every part, and the ends must be crossed over the sound skin. If suppuration is profuse, they should be changed every two days, at first: in ordinary cases every three or four days is sufficient. In the fourth degree, before the eschars are detached, the straps should remain for five or six days; the discharge which escapes between them being absorbed by charpie, and the whole surmounted with some compresses and a roller: when changed, the wounds should be cleansed, and even washed with saturnine lotion. No portion of detached epidermis should be left. If the surface of the part burned is uneven, the inequalities must be filled with charpie, or compresses, placed between the strapping and the roller. This treatment is only applicable for the arms and legs, and must be suitably modified for the hands and feet. In very large burns it is not advisable, as the dressing would be inconvenient and difficult: some skins also will not bear it.

The composition of the plaister is important: the linen should be neither too

fine nor too coarse; neither too thickly or too thinly covered. That diachylon is best which has less resin and fat, and more lead. The effect of this treatment is astonishing. Burns of the limbs generally are cured in three or four dressings. The cicatrix in many respects is remarkable: it forms on all points of the surface, denuded to the second degree, at the same time; so that on the first or second removal of the straps it looks large, smooth, and supple, but firm. In the third degree the same thing is observed, the new skin forming in the centre of the suppurating wound, as well as around its edges. [M. Velpeau considers this remarkable, "*une particularité*," but John Hunter has described it as the usual mode in which ulcerations heal, where the *whole* thickness of the skin has not been destroyed.] If the ulcer is deeper, its edges soon subside, become white, and then prolonged by a kind of pale thin pellicle over the suppurating surface. The granulations become firm, and are soon replaced by an epidermic surface, even before the bottom of the wound is on a level with its edges, so that the cicatrix remains a long time depressed. As the cicatrix is not formed wholly from the circumference to the centre, and is soft, of equal thickness, and very extensible, it is free from bridles, and irregular and deformed lumps, which follow other modes of cure. As they are less exposed to break and to excoriate, the consecutive retractions are more often avoided.

The duration of the treatment is almost the same in large as in small wounds. When well done, it gives no pain nor irritation: no dressing is so pleasant; and immediate relief follows. As it is changed only every three or four days, it is extremely inexpensive.

The details of sixteen cases are given, illustrating the effects of this treatment, and proving the previous statements. Some of these also prove that cicatrization takes place as rapidly in an ulcer of some standing, as when the surface is first exposed. No other treatment but this is equally suitable in all stages. In order to discover on what the beneficial effects of this treatment depended, M. Velpeau made numerous comparative experiments: thus, to try if the compression was the agent, he tried on the same patient compression by bandages, covering the wound with different dressings, but the burns which were strapped healed more rapidly: he next tried strapping with other plaisters, but the diachylon succeeded much more rapidly: finally, he compared the effect of covering the burns with disks of diachylon and other plaisters, without making pressure; and they healed more rapidly under the use of diachylon, but less so than when pressure was used. The union of pressure and the diachylon plaister is therefore essential. It is needless to state that this is merely an application to burns of Baynton's mode of treating ulcers; M. Velpeau has, however, applied it to ulcerations of all kinds, and even to subcutaneous inflammations and indurations. He proposes to return to this part of his subject at another period.—*British and Foreign Medical Review, from the Revue Médicale Française et Etrangère, Juin et Juillet*, 1835.

DESCRIPTION OF A NEWLY INVENTED INSTRUMENT,

Applicable to the Cure of Fractures of the Jaw.

By Francis L'Estrange, A.M. M.R.C.S.

All practical surgeons have lamented the inefficacy of our means in adjusting or setting certain fractures of the lower jaw; indeed, the most simple are attended with a vast deal of troubled to the surgeon, and by no means proportionate advantage to the patients; for the patient is *bandaged up*, having some firm unyielding substance between his teeth, or the upper jaw is made the splint or support. In this latter case, it is obvious that the patient cannot take sustenance without displacing, more or less, the bandage, or by the extraction of one or more of the incisors. In any case it is extremely difficult to keep the mouth properly cleansed; but in fractures engaging the posterior part of the lower jaw, all our means of adjustment have been hitherto only partially successful, and considerable deformity continues. Now it is to fractures of this latter kind that I wish particularly to call the attention of the profession: two such fractures have lately occurred in this city, one under the care of the surgeon general in the Meath Hospital, the second under Professor Harrison, in the city of Dublin Hospital, which have succeeded quite to the satisfaction of both gentlemen. The apparatus employed for setting these fractures was an instrument invented by me, which, for simplicity and efficacy, is, I think, likely to prove of great advantage. In the application of this instrument, we have no occasion for bandages; we have a full view of the fracture, the patient can take any fluid, can express his wants, and the mouth can be cleansed at pleasure without interrupting the cure. I shall here give a short description of the instrument, and regret that it is not in my power at present to submit a drawing, as I was obliged to take it asunder to make some slight altera-

tions; but the principle on which the first was constructed shall be retained in the new instrument. I beg to premise a few observations on the nature of this fracture: it occurred between the tricuspidate or anterior molars; the anterior portion remained in its natural position, whilst the posterior was drawn considerably inwards towards the mesial line, so that the superior molars overlapped the inferior: it is therefere manifest, that if the fracture healed in this unnatural position, the food could not be masticated, or at least very imperfectly so at this side of the mouth. What, then, was to be done to obviate this deformity? Clearly to push outwards the posterior portion of the fracture, and to retain it in its normal situation till bony union had taken place. In this attempt I have succeeded by the instrument, the description of which I here subjoin, and hope in your next publication to be able to submit the drawing to your notice:—

The instrument is made of German silver, about four inches in length; it can be made to expand about three inches or more, and consists of a double pair of callipers, with a flat joint in the centre, which divides the instrument into two equal parts, which we may call the internal (as they are for the mouth), and external shanks: the internal are flat, bowed, taking the shape of the horizontal ramus of the lower jaw, and intended to lie on the teeth; the external shanks are bent downwards at an obtuse angle, to rest on the chin, with a screw attached, which *divaricates* or closes both shanks, as circumstances may require. To the internal edges of the internal shanks is attached a flat plate of silver of a semicircular shape, about an inch in length and half an inch in depth: to the external surfaces of these plates are soldered, at their inferior edges, a short silver pin, set off at right angles, which is intended to pass between the interstices of any two teeth, for the purpose of fixing the instrument, and preventing its displacement by the gangrene. Its mode of application is very simple: the internal shanks are introduced closed into the mouth, by using the screw attached to the external; the internal legs are divaricated, and the silver pin fixed in the interstices of the opposite and corresponding teeth. As the internal shanks expand, they force outwards the posterior portion of the fracture till it is adjusted to the anterior portion. The internal shanks of the instrument remain in the mouth without inconvenience to the patient, as they do not interfere with the motions of the tongue; and the lips being brought together at pleasure, prevent the overflow of saliva.

In conclusion, I may here observe, that this instrument is also applicable to the treatment of the simple fracture, where the portions deviate merely from the same horizontal plane; but in this latter species of fracture, we require as an auxiliary an instrument which I invented some years ago; but of this more on a future occasion.—*Dublin Journal*, May, 1836.

REMARKABLE BIRTH-DAYS.

Dr. Graves (Dublin Journal) has selected from some of the German almanacks, a list of birth-days of eminent living authors. The following are probably the most remarkable amongst them:—

Blumenbach, Gottingen, May 11, 1752.
Tiedemann, Heidelberg, Aug. 23, 1781.
Trommsdorf, Erfurt, Apr. 2, 1770.
Rose, Berlin, Aug. 6, 1796.
Mitscherlich, Berlin, Jan. 17, 1794.
Ehrenberg, Berlin, Apr. 19, 1796.
Rust, Berlin, Apr. 5, 1775.
Callisen, Copenhagen, Apr. 8, 1786.
Himly, Gottingen, Apr. 30, 1762.
Gräfe, Berlin, Mar. 8, 1787.
Carus, Dresden, June 3, 1789.
Burdach, Königsberg, June 12, 1776.
Weber, Leipzig, June 24, 1796.
Schultz, Berlin, July 8, 1796.
Valentin, Breslau, July 8, 1810.
Nägele, Heidelberg, July 12, 1778.
Müller, Berlin, July 14, 1801.
Hufeland, Berlin, Aug. 12, 1762.
Oppenheim, Hamburg, Oct. 5, 1799.
Purkinje, Breslau, Oct. 17, 1790.
Brandes, Salzuflen, Oct. 18, 1795.
Ideler, Berlin, Oct. 25, 1787.
Langenbeck, Göttingen, Dec. 8, 1776.
Hecker, Berlin, Jan. 5, 1795.
Froriep, Berlin, Feb. 21, 1804.

DEAFNESS CURED BY GALVANIC CURRENTS.

At a recent sitting of the Academy of Sciences, M. Magendie gave an account of a young Polish officer who, at the battle of Ostrolerka, in charging a battery which fired cannon shot, was struck down, though he received no bruise in any part of his body; he remained senseless for nearly half an hour. On reviving a little, it was found that he had lost his hearing, speech, and taste. He was for some time treated at Vienna with repeated bleedings and counter-stimulants, but without success; at Trieste, strychnine was employed by the endermic method, just as fruitlessly. He then came to Paris, where M. Magendie proceeded to remedy the deafness by galvanic currents, one of the wires of the pile being applied over the chorda tympani. At the very first trial an encourag-

ing effect was produced: the patient heard a loud buzzing noise in his head. At the third application the sense of taste began to be re established,—a fact of much interest for the anatomist and physiologist, as it throws light on the origin of the chorda tympani and the functions of the fifth pair. After seven or eight applications of the same sort, the patient could hear a drum, a bell, and at last the human voice. Still, however, the tongue is incapable of voluntary movement, though it is expected that the cure will be eventually complete by the means already adopted, and applying the conducting wires to the laryngeal nerves.—*Gaz. des Hôpitaux.*

TORSION OF ARTERIES IN OPERATIONS ON THE NECK OF THE UTERUS.

M. Amussat has communicated to the Royal Academy of Medicine the details of an operation in the neck of the uterus, in which extirpation was performed for cancerous disease; a strong jet of arterial blood occurring, M. Amussat seized the vessel, and performed torsion with instantaneous success. He is the first surgeon who has thus operated on the uterine arteries. It is of importance that the vessel should at once be seized, for if the uterus be allowed to re ascend, it becomes extremely difficult to discover the orifices of the divided arteries.—*Archives Générales.*

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, May 10, 1836.

H. Earle, Esq., F.R.S., President, in the Chair.

The evening was occupied with the reading of an interesting and valuable paper by Sir Benjamin C. Brodie, on *Injuries and Diseases of the Spinal Marrow.* As the concluding portion of the paper is reserved for Tuesday next, we shall reserve our account of it for another occasion.

NEW MEDICAL WORKS.

Outlines of Human Pathology. By H. Mayo, F.R.S. &c. 8vo. 18s. cloth.

Lee's Celsus, Latin and English; with Order of Construction, &c. Vol. 2, 8vo., 18s. bds.

An Introduction to Phrenology, in the form of Question and Answer. By Robert Macnish. 18mo. pp. 186, 2s. 6d.

The Practical Anatomy and Elementary Physiology of the Nervous System; designed for the Use of Students in the Dissecting room. By F. Le Gros Clark, Demonstrator of Anatomy in St. Thomas's Hospital. 1 vol. 12mo.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

May 19, 1836.

George Pink, Eastmeon.
Robert Wright, Rastrick, Halifax.
Samuel Barrett, Bideford.
William Strong, Bridport, Dorset.
Arthur Beroni Evans.
Arthur Tibson.
John Blackburn, Liverpool.
James Johnson, Lancaster.
Samuel Harris, Fenchurch street.
William Price Evans, Crickhowel, Breconshire.
James Bower Harrison, Manchester.
Edward Morse, Norwich.

NOTICE.

Mr. Blyth's letter has reached us, but we cannot give it insertion: controversial matter, without any new facts, would afford but little entertainment to our readers. Besides, Dr. Cowan would be entitled to a second reply.

The papers of several correspondents have been received: next week they shall be more fully acknowledged.

Wilson & Son, Printers, 57, Skinner-St. London.

LECTURES ON MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

By Jon. Pereira, Esq., F.L.S.

Lecture XXXV.

Copper, and its *preparations*, next deserve our notice.

COPPER.

History. — Cuprum, or copper, received its name κύπρος, from the island of Cyprus, where it was first discovered, or at least worked to any extent. It seems to have been known in the most remote ages of antiquity, for Moses speaks of brass (an alloy of copper and zinc). The alchymists called it Venus, "that is," says Boerhaave, "*meretrix publica*, a common prostitute, in consequence of its solubility in so many liquids."

Native state.—It is met with in both the organized and inorganized kingdoms. Thus it has been found in the *delphinium staphisagria*, *krameria triandria*, *conium maculatum*, and many other plants. The ores of this metal may be arranged under seven heads—*native copper*, *the oxides*, *the sulphurets*, *the seleniuret*, *arseniet*, *chloride* or *muriate*, and the *oxysalts* of copper (namely, the carbonate, arseniate, phosphate, sulphate, and silicate).

Preparation. — Copper is obtained by roasting the sulphuret, and afterwards smelting; these processes are repeated several times until the metal becomes sufficiently pure. It is then refined or toughened by melting and stirring with a birch pole.

Properties.—It is a crystallizable, brilliant, red metal, having a specific gravity of 8·895; malleable and ductile; it has a nauseous, styptic taste, and a peculiar disagreeable smell. Chemists are not agreed as to its atomic weight: Dr. Thomson adopts 32, and I shall follow him.

Characteristics.—Copper is easily recognized by its colour, by its communicating a green tinge to flame, and by its solution in nitric acid, possessing the following properties: it is blue, or greenish blue; potash, or soda, occasions a blue precipitate of the hydrated peroxide of copper; a small quantity of ammonia produces a similar bluish white precipitate, but an excess redissolves it, forming a deep blue liquid: ferrocyanuret of potassium occasions a reddish brown precipitate of the ferrocyanuret of copper; the hydrosulphurets throw down the black sulphuret; and, lastly, a polished iron plate plunged into the liquid, becomes covered with copper.

Physiological effects.—Metallic copper appears to produce no pernicious effects when taken internally, so long at least as it retains its metallic state, as many cases are recorded where coins of this metal have been swallowed and retained for a considerable time without any ill effects arising, and Drouard gave as much as an ounce of finely powdered copper to dogs of different ages and sizes, but none of them experienced any inconvenience.

Notwithstanding these facts, however, various effects have been attributed to it. Thus, Cothenius says, copper filings operate by stool, urine, and saliva, and the late Professor Barton was accustomed to relate an instance of a child, who, having swallowed a cent, continued for some time to discharge several pints of saliva. Lastly, Portal mentions a case in which copper filings, incorporated with crumb of bread, acted powerfully on the system. I have no doubt but that the effects here mentioned arose from the oxidation of the metal by the acids of the alimentary canal.

Use.—Copper filings, in doses of three or four grains, were formerly used in rheumatism, and also as an antidote against the effects of the bite of a mad dog.

Cupreous Preparations.

Physiological effects.—Before examining the preparations of copper individually, I shall speak of them collectively. Copper is a metal readily oxidated, and in the form either of oxide or salt is a powerful poison. Acid, alkaline, saline, and fatty bodies, promote its oxidation when placed in contact with it in the air, and by dissolving a portion of the newly formed oxide, acquire poisonous properties.

If the cupreous preparations be used in *very small* doses, they sometimes give relief in certain diseases (principally of the nervous system), without obviously affecting the functions; in other words, in these instances the only apparent effect is the modification observed in the morbid condition. These are the cases in which these preparations have been termed *tonic*, *antispasmodic*, or *alterative*, according to the nature of the disease; thus, in ague they have been termed tonic, in epilepsy antispasmodic, in dropsy alterative. The beneficial operation is presumed to be owing to some influence exerted by the remedy over the nervous system. The effects produced by the long-continued use of small doses of the preparations of copper have not been satisfactorily determined; they are said to be various affections of the nervous system (such as cramps or paralysis), alteration of the colour of the skin, chronic inflammation of the respiratory and digestive apparatus, slow fever, and wasting of the body. These symptoms constitute what has been termed *slow*, or *chronic poisoning by copper*. The smelters and workers in copper do not suffer from the vapour or emanation of this metal, as the workmen employed in the preparation of mercury, of arsenic, or of lead, do, from the vapours of these metals; this, indeed, might be expected, when we consider how much more volatile the latter and their preparations are, than copper and its compounds. In *larger*, or full medicinal doses, these remedies act as *emetics*, exciting speedy vomiting, with less nausea than tartar emetic produces. In *still larger* quantities these bodies act as poisons, giving rise to gastro-intestinal inflammation, and disordering the functions of the nervous system (especially the cerebro-spinal portion), constituting *acute poisoning by copper*. The usual symptoms are, a coppery taste, eructations, violent vomiting and purging, griping pains, cramps in the legs and thighs, headache, giddiness, convulsions, and insensibility: jaundice is occasionally observed. In some cases the cerebro-spinal symptoms precede those which indicate inflammation of the alimentary canal. In experiments made on animals, it has been observed that death was sometimes produced, without any marks of local irritation; the symptoms being those indicative of a disordered condition of the nervous system. By some toxicologists these preparations are ranked among the *irritant* poisons, though Buchner, judging from Reiter's experiments, terms them *astringent*.

Drouard, and others, were of opinion that the preparations of copper do not become absorbed, but Lebkuchner has detected copper in the blood of the carotid artery of a cat, into whose bronchial tubes he had injected four grains of the ammoniacal sulphate; and Wibmer has found it in the liver of animals to whom he had given the acetate for several weeks.

Post-mortem appearances.—In animals killed rapidly by these poisons, no morbid appearances are found, in consequence of death being produced by their action on the nervous system; but when the death was slow, marks of gastro-intestinal inflammation, and occasionally indications of inflammation of the brain, have been observed.

Uses.—These preparations are used both as external and as internal remedies; externally as stimulants, astringents, styptics, and caustics; internally, as emetics and tonics, or antispasmodics. The particular cases will be noticed in speaking of the individual preparations.

Antidotes.—The chemical antidote for the cupreous preparations is *albumen*; hence, the whites of eggs, and in the absence of these, milk, or even wheaten flour, should be employed. *Iron filings* have been proposed by Navier, by Payen and Chevallier, and subsequently by Dumas and Milne Edwards. The iron decomposes the cupreous salt, and precipitates the copper in the metallic (and, therefore, in an inert) state. The *ferrocyanuret of potassium* is also said to be a good antidote: a drachm or two of it may be taken with safety, for it is not so poisonous as was at one time imagined. *Sugar* was proposed by Marcelin Duval as an antidote; its efficacy, though denied by Orfila and Vogel, has been lately reasserted by Postel. The alkaline sulphurets formerly used are worse than useless, since they are active poisons. The inflammatory symptoms are of course to be subdued by the usual means.

Sulphate of Copper.

History and synonymes.—It was known to the Greeks and Romans, and is mentioned by Pliny. It has had various names, as *blue vitriol*, the *deuto-* or *bi-sulphate of copper*, &c.

Native state.—In copper mines, the sul-

phuret of copper becoming oxidized by the combined influence of the air and water, is converted into the sulphate, which is found dissolved in the waters in, or issuing from, these mines; these cupreous solutions are termed *waters of cementation*.

Preparation.—One method of obtaining this salt is to evaporate the water issuing from copper mines. Another, is to roast copper pyrites, lixiviate the residuum with water to dissolve the sulphate formed, and then crystallize. Other methods are sometimes followed, but I do not think it necessary to detail them.

Properties.—This salt occurs in fine blue crystals, the primitive form of which is the doubly oblique prism. Its taste is styptic and metallic. When exposed to the air the crystals effloresce slightly, and become covered with a greenish white powder; when heated they give out water, and, if the temperature be sufficiently high, the acid is expelled, leaving the oxide of copper. One part of this salt requires nearly twice its weight of water at 60° to dissolve it.

Composition.—It is composed of—

1 atom peroxide copper ..	=	40
1 atom sulphuric acid....	=	40
5 atoms water .... 5 × 9	=	45
		125

Its symbol, therefore, is, $\dot{Cu}\ \dddot{S}\ 5\dot{H}$.

Characteristics.—These are the tests for sulphuric acid, and for the cupreous preparations, before mentioned.

Physiological effects.—In *very small doses* it has no sensible operation on the body, though it occasionally ameliorates certain diseases, such as epilepsy and ague; and it has been denominated in these cases antispasmodic and tonic. In *larger doses* it is a safe and useful emetic, acting very speedily, and without exciting any great disorder of the general system. In *excessive doses* it becomes a poison, producing inflammation of the alimentary canal, and disordering the functions of the nervous system, as noticed when speaking of the cupreous preparations generally. The *local* action of this salt is astringent, styptic, and caustic.

Uses.—As an *external* agent, we often use it in substance as an application to ulcers, either for the purpose of repressing excessive soft and spongy granulations, commonly denominated "proud flesh," or of hastening the process of cicatrization; and for either of these purposes it is one of the best agents we can employ. Solutions of it are frequently applied to mucous membranes, to diminish excessive secretion: thus to the conjunctiva, in chronic ophthalmia, and to the mucous lining of the vagina or urethra, in discharges from these parts. In superficial ulcerations of the mucous membranes (especially of the mouth), one or two applications of the sulphate of copper, in substance, are generally sufficient to heal them. As a styptic, a solution of this salt is sometimes used to repress hæmorrhages from a number of small vessels. Rademacher applied with good effect brandy impregnated with sulphate of copper, in a case of alopecia, or baldness, which occurred in a young man.

Internally it is employed as an *emetic*,—for example, in narcotic poisoning; but for ordinary purposes it is less adapted for exciting vomiting than many other emetics, particularly tartarized antimony. As an *astringent* it is used in chronic ulceration of, and increased secretion from, the mucous membrane lining the alimentary canal; and also to check excessive secretion from the mucous lining of the bronchial tubes and cells. In repeated small doses it has likewise been used in epilepsy, chorea, ague, dropsy, &c.

Administration.—The dose of it, as an emetic, is from three or four grains to fifteen; as an astringent or tonic, from a quarter of a grain to one or two grains. Solutions used for external purposes vary considerably in their strength in different cases, but usually from one or two grains to eight or twelve, dissolved in an ounce of water.

Cuprum Ammoniatum.

History.—This compound was introduced into practice in this country by Dr. Cullen.

Preparation.—In the London Pharmacopœia it is prepared by rubbing half an ounce of sulphate of copper with six drachms of the hydrated sesquicarbonate of ammonia until effervescence ceases, and then drying the ammoniated copper, wrapped in bibulous paper, with a gentle heat.

Theory.—The above proportions are very nearly two atoms of the sulphate, and six atoms of the sesquicarbonate. When the two salts are rubbed together, part of their water of crystallization is set free, which renders the mass moist; at the same time a portion of the carbonic acid of the sesquicarbonate of ammonia escapes, producing the effervescence alluded to; and the compound becomes of a deep azure-blue colour. The further changes are not accurately ascertained; it is probable, however, that the sulphate of copper is deprived of part of its sulphuric acid by the ammonia combining with it to form sulphate of ammonia; which combines with the

subsulphate of copper, thus produced, to form a *double sulphate of copper and ammonia*. There is, however, an excess of the sesquicarbonate of ammonia, and it is not improbable that this may combine with some oxide of copper to form a *double carbonate of copper and ammonia*.

Properties.—This compound has a deep blue colour, a styptic metallic taste, and an ammoniacal odour. It is soluble in water; but unless there be an excess of the sesquicarbonate of ammonia, the solution, if much water be present, deposits some hydrated oxide of copper.

Composition.—This compound consists of—

Oxide of copper.
Ammonia.
Sulphuric acid.
Carbonic acid.
Water.

But the proportion of these ingredients, and their mode of combination, are not ascertained. It is probably a mixture of *cupreous sulphate of ammonia*, and the *cupreous carbonate of ammonia*.

Characteristics.—The odour of this compound (which is increased by the addition of caustic potash or lime) will easily detect ammonia. A solution of it may be shewn to contain sulphuric acid by the addition of a barytic salt (chloride or nitrate). The presence of copper may be determined by the colour of the preparation, and partly by applying the tests for copper already described.

Physiological effects.—The operation of this preparation is for the most part the same as the sulphate, with the exception, perhaps, that its local action is less powerful, so that somewhat larger quantities of it may be taken at a dose.

Uses.—It has been employed *locally* in the form of solution, as a collyrium, in opacities of the cornea. *Internally* it has been used in affections of the nervous system, from its supposed specific action on this part; thus in epilepsy, catalepsy, chorea, spasmodic asthma, cramps of the stomach, &c. It has also been administered in ague, in dropsy, and as a preservative from the effects of the bites of rabid animals.

Administration.—It may be administered internally in doses of half a grain, gradually increased to five grains. In the Pharmacopœia there is a *solution* for external purposes, composed of a drachm of the ammoniated copper to a pint of distilled water; but it requires dilution before applying it.

Verdigris, or the Subacetate of Copper.

History and synonymes.—This salt, termed sometimes *ærugo*, or, *rough verdigris* (to distinguish it from another acetate presently to be mentioned), was known to the ancients.

Preparation.—At Montpellier it is thus made: the refuse of grapes is allowed to ferment with sour wine, and is then laid in alternate strata with plates of copper. In about fifteen days these plates are covered with the acetate of copper; they are then wetted, and exposed for a month to the air; the acetate absorbs the water, and uniting with more oxide of copper forms a subacetate, which is scraped off, and packed in leathern sacks for exportation. At Grenoble, verdigris is obtained by sprinkling plates of copper with ready-made vinegar.

Properties.—It is met with in a pulverulent or massive form, of a blue or rather greenish-blue colour, varying somewhat in its tint. Its taste is astringent and metallic; its odour is somewhat similar to that of acetic acid, but more disagreeable.

Composition.—It is essentially a compound of acetic acid and oxide of copper; but it sometimes contains also carbonic acid. Dumas says, when verdigris is of a light blue colour, it is a *subsesquiacetate*; but when greenish, a *diacetate*. Both kinds are *hydrates*.

Characteristics.—When digested with strong sulphuric acid it evolves the odour of acetic acid. If boiled in distilled water a solution is obtained, known to contain copper by its colour, and by the tests already mentioned for the cupreous preparations.

Physiological effects.—The action of verdigris on the system is very similar to that of the other preparations of copper: thus, taken in small and repeated doses, it appears to act on the nervous system; in larger doses it operates as an emetic; and, in excessive doses, is a powerful poison, producing both gastro enteritis (indicated by vomiting, purging, and pain), and an affection of the nervous system, marked by insensibility, convulsions, and even tetanus.

Uses.—The operation of verdigris on the system being somewhat variable, it is rarely administered by the stomach. As an external application, it is used in the form of powder, of cerate or ointment, and of oxymellite. The *powder* is sprinkled over foul and indolent ulcers, or, mixed with powdered savin, is applied to destroy venereal warts. The *oxymellite of verdigris*, formerly termed *mel Ægyptiacum*, and now called in the Pharmacopœia the *linimentum æruginis*, is employed to stimulate ill-conditioned sores; thus it is applied to the venereal ulcers of the throat, by means of a camel's hair pencil, or diluted with water and used as a gargle.

PLUMBUM, OR LEAD.

History. — This metal, termed by the Greeks μολιβδος, or μολυβδος (whence, probably, the Latin term *plumbum*) appears to have been known at a very early period, for Moses, in the nineteenth chapter of Job, alludes to it, as being used for making inscriptions on—a practice which seems at one time to have been in general use among the orientalists, for Mr. Taylor has referred to accounts of several books of lead found in Eastern countries.

Native state.—Lead is found in the *metallic* state, in the form of *oxide* (both free and combined, as in the *oxy-salts*), *sulphuret*, *seleniuret*, and *chloride*.

Extraction.—It is extracted from the sulphuret called *galena*, which is first roasted in reverberatory furnaces, by which means it is converted into a mixture of sulphate and oxide, and then smelted with lime and coal (the first acting as a flux, the second as a deoxidizing agent.)

Properties.—The physical properties of lead are too well known to require much description. By exposure to the air, it becomes tarnished by the formation of a thin coat of oxide, which, uniting with carbonic acid, forms the carbonate.

Pure distilled water has no action on lead, if the gases (as air and carbonic acid) be excluded; but if these be admitted, a thin crust of carbonate is soon formed. It is remarkable that the presence of most neutral salts—sulphate of soda and chloride of sodium, for example—impairs the corrosive action of air and water. Hence, therefore, we can easily comprehend the reason why leaden cisterns and pipes do not more frequently give a metallic impregnation to water; and why rain-water is more apt to become impregnated with lead than spring-water. The latter, however, by long keeping in leaden vessels, may also become contaminated with lead.

Characteristics.—If lead be dissolved in nitric acid, we may easily recognize its presence in the solution by the following characteristics: — Alkalies, their carbonates, sulphuric acid and the sulphates, and ferrocyanuret of potassium, produce white precipitates when added to the solution; chromate of potash and iodide of potassium occasion yellow precipitates; sulphuretted hydrogen and the hydrosulphurets form black precipitates of the sulphuret of lead; lastly, a piece of zinc throws down metallic lead in an arborescent form.

Physiological effects.—I believe, that so long as lead retains its metallic form, it is inert. In a French journal, we are told that three ounces and six drachms of this metal have been given to a dog without any obvious effects. As, however, it is a metal which is readily oxidated, it occasionally proves active when swallowed, in consequence of its being acted on and oxidized by the contents of the alimentary canal. An instance of this kind is mentioned by Paulini, in which colic was produced by swallowing a leaden bullet. Proust says, that the alloy of lead and tin may be swallowed with impunity, in consequence of its being much less easily oxidated than the pure metal.

Use.—Metallic lead is now never employed in medicine, though balls of this metal were formerly exhibited in ileus.

Preparations of Lead.

Physiological effects.—The preparations of lead are, for the most part, energetic poisons. The *sulphuret*, however, appears to be inactive, or nearly so; for Orfila have given an ounce of it to dogs without observing any ill effects; four ounces have even been given to horses without any unpleasant results. Mr. Braid states, that the workmen who dig and pulverize the ore (sulphuret of lead), at the lead-mills, in Lancashire, never have the lead colic until they work at the smelting furnaces. *Sulphate of lead* is also inactive, or nearly so; at least, Orfila gave large doses of it to dogs with impunity.

Most, if not all, the other preparations are more or less active; the effects and symptoms, however, vary with the dose.

In *small doses* these preparations act on the alimentary canal as astringents; checking secretion and causing constipation. These may be regarded as the local effects. When absorbed, the constitutional effects of lead are observed: the arteries become reduced in size and activity, for the pulse becomes slower and smaller; the temperature of the body is diminished; and sanguineous discharges, whether natural or artificial, are frequently checked, or even completely stopped. This constringing and sedative effect seems extended to the secreting and exhaling vessels; the discharges from the mucous membranes, the exhalation from the skin, and the urine, being diminished in quantity. Thus we observe dryness of the mouth and throat, thirst, greater solidity of the alvine evacuations, diminution of the bronchial secretion, and of cutaneous exhalation, which is particularly noticed in patients suffering with colliquative sweating. From all these circumstances, it would appear these preparations give rise to a contracted state of the coats of the blood-vessels (at least of the arteries). It is not at all improbable that the coats of the absorbents are similarly affected, as has been asserted. If this be the case, some obstruction would probably be offered to the passage of lymph; the

functions of absorption would be carried on with less energy, and the lymphatic glands would perhaps become in consequence affected. The wasting of the body produced by lead in these small doses, has been denominated *tabes saturnina*, or *tabes sicca*.

The long-continued use of the preparations of lead rarely fails to give evidence of its effect on the muscular and nervous systems; and which is manifested by a curious train of symptoms, commencing with colic, and terminating in palsy or apoplexy. *Lead* or *painter's colic* is variable in its mode of attack; at one time commencing suddenly, and without any very marked premonitory symptoms, at another being preceded by dyspeptic symptoms—such as diminished appetite, with a painful and constipated state of the bowels, the fæces being very hard. During an attack, there is usually obstinate constipation, with acute pain, much increased at intervals; but sometimes a relaxed condition of the bowels has been met with. Merat refers the continued pain to the small intestines, while the more violent and intermitting kind resides principally in the transverse portion of the colon. Pressure rarely increases, and very commonly relieves, the pain. Cases, however, do occur (and I have seen several) in which there is great tenderness of the bowels. The abdomen is strongly retracted, sinks in about the navel, and feels very hard. To these symptoms may be added vomiting, cramps of the lower extremities, hard and generally slow pulse, though sometimes it has been found frequent.

Merat says, that on examining the bodies of patients who have died affected with lead colic, he found a contracted condition of the colon, and this he considers to be the seat of the disease; but the observations and reasoning of Dr. Abercrombie on ileus render Merat's opinion doubtful. It appears that, in fatal cases of ileus, one part of the intestine is generally found in a state of distention, and another part empty and collapsed, presenting nearly the form of a cord; and several reasons which you will find detailed in Dr. Abercrombie's work lead us to conclude that the collapsed or contracted state is the natural condition of healthy intestine when empty, and that the distended portion is the primary seat of the disease, the distention arising from a paralytic condition of the muscular fibres, whereby it is unable to contract and propel its contents onward. Now this view of the case is the more probable, since the action of lead on the muscular fibres of the intestine is regarded as of the same kind as that on the fibres of the voluntary muscles afterwards produced. Moreover, I ought to add that this contracted condition of the intestinal tube has not always been found after death from colica pictonum. Andral and Louis have reported cases in which no lesion could be discovered; some have found intus-susception, others have noticed marks of inflammation.

Another effect of poisoning by lead is an affection of the cerebro-spinal system, generally manifested by *paralysis*, but occasionally by giddiness, convulsions, and coma, and now and then by apoplexy. The palsy may occur without colic, or it may come on while the patient is suffering with it, but in general it succeeds colic. It may happen in both upper and lower extremities, though more frequently in the former; and it affects the extensor more than the flexor muscles, so that the hands are generally bent on the arms, which hang dangling by the side. Frequently pain is experienced in the paralyzed part, and sometimes in the region of the spine also. On examining the bodies of persons who have died with this disease, no lesion has hitherto been discovered in the spinal marrow. The muscles of the affected limb are observed to be wasted and very pale, and have sometimes the appearance of a white fibrous tissue.

In *very large doses*, some of the plumbeous preparations (the acetate, for example) act as irritant poisons; giving rise to the usual symptoms indicative of gastro-enteritis. However, none of them equal, in the intensity of their local action, the mercurial or even the cupreous compounds.

Modus operandi.—There are some theoretical points connected with the operation of lead, which I now proceed to examine. And in the *first* place, *do the active salts of lead become absorbed?* Analogy would lead us to answer this question in the affirmative; and Tiedemann and Gmelin have proved the truth of this presumption, by detecting lead in the blood of the splenic, mesenteric, and hepatic veins of dogs killed by the acetate of lead; and they also found it in the contents of the stomach and intestines, but neither in the chyle nor urine. Wibmer has detected it in the liver, the muscles, and particularly in the spinal cord. In the *second* place, *on what parts of the body do these preparations exert any specific influence?* Principally, I believe, on the nervous system; for several circumstances lead us to suspect that lead colic even is primarily an affection of the nervous system; perhaps of the ganglionic or spinal portion, and that the affection of the muscular fibres of the intestine is secondary. That the spinal marrow becomes subsequently affected seems proved by the paralysis of

the extremities, and the pain in the course of the spine. In the latter stages, however, the brain appears to be affected: hence the occasional giddiness, coma, or apoplexy.

The constitutional effects of lead may be produced in various ways; as, when taken with articles of food and drink into the stomach; when inhaled in the form of dust or vapour with the air; when applied to mucous membranes, ulcers, &c. Hence the persons most liable to these effects are those whose occupations bring them in contact with this metal; for example, painters, plumbers, roasters and smelters of lead, the manufacturers of the plumbeous preparations, glass-blowers, potters, lapidaries, &c.

Dr. Anthony Todd Thomson* is of opinion, that carbonate of lead is the only preparation of this metal that can produce colic; and though he has, I think, clearly shewn that lead colic more frequently arises from the carbonate than from any other salt of lead, he has, in my opinion, failed in proving that no other preparation of lead *can* produce it. Indeed, if his opinion were true, it would constitute an exception to the general effects of the metallic preparations; for we do not find that the specific effects of arsenic, or of mercury, or of copper, or of antimony, are produced by one preparation only; so that, *à priori*, analogy is against the opinion. Furthermore, it is well known that the vapour of the oxide of lead taken into the lungs may produce colic, and that the ingestion of the acetate, citrate, or tartrate of lead, is capable of exciting the same effect. Now Dr. Thomson explains these facts by assuming that the oxide of lead unites with carbonic acid in the lungs, and thus is converted into carbonate; and that the acetate, citrate, and tartrate, are decomposed in the alimentary canal, and converted into carbonates. But it appears to me much more simple and consistent with analogy, to admit that these preparations are of themselves capable of producing colic, than to assume that they undergo the changes here supposed. Moreover, in some instances in which colic was produced, it is unlikely that these changes could have occurred, owing to the excess of acid taken with the salt of lead.

The *uses* of the preparations of lead will be best discussed in speaking of the individual compounds.

Antidotes.—Poisoning by lead usually puts on one of three forms, *irritant poisoning*, *lead colic*, and *paralysis*.

1. *Irritant poisoning.*—Administer diluents, holding in solution some sulphate, (as sulphate of soda, of magnesia, or of potash or alum) so that a sulphate of lead may be formed. If vomiting have not already come on, tickle the throat, and administer emetics of the sulphate of zinc or of copper, or the stomach-pump may be employed.

2. *Lead colic.*—In this country lead colic is usually treated by the combined use of purgatives and anodynes, the purgatives being either castor oil, or salts and senna, the anodyne being opium. When the vomiting is very troublesome, and liquid medicines do not remain on the stomach, we may give the compound extract of colocynth, with opium, in the form of pill. In several cases in which the pulse was full and strong, the face flushed, and the tongue furred and dry, I have used bloodletting with evident advantage. The sulphates have been recommended, as also mercury.

3. *Lead paralysis.*—Nux vomica, and its active principles strychnia and brucia, are perhaps of all internal remedies most deserving of trial, because of their specific effect on the spinal marrow; and the chance of their success is, of course, much increased by the circumstance of there being no discoverable lesion of this portion of the nervous system. Mercury is another remedy that has been recommended. Various local measures have been tried, but without much benefit; for example, electricity, and irritants, such as ammonia and cantharides.

Litharge, or Semi-vitrified Oxide of Lead.

History. — This compound has been known from the most ancient times. It seems to be the substance which Pliny, in one part of his work, (Lib. xxxiv. 53) terms *molybdæna*.

Preparation. — Litharge is usually a secondary product obtained during the cupellation of argentiferous lead. This process you will find described in Watson's Chemical Essays.

Properties.—It occurs in the form of small yellow or reddish scales or flakes. According to its colour, it is termed either *silver* or *gold litharge*.

Composition.—It consists essentially of the protoxide of lead, which is composed of

1 atom lead	104
1 atom oxygen....	8
	112

But it is not impossible that the redder kinds may contain a small portion of peroxide of lead in combination with some protoxide, forming a kind of plumbate of lead.

* See MEDICAL GAZETTE, vol. v. p. 538; and vol. x. p. 689.

Characteristics.—Heated on charcoal by the blowpipe, it is readily reduced to the metallic state. Digested in nitric acid, we obtain a solution which may be easily recognized to contain lead, by the tests already mentioned for this metal.

Physiological effects.—Inhaled in the form of vapour or fine dust, it is capable of producing the constitutional effects of the preparations of lead already described. The effects of this preparation when swallowed are but little known. From its external use, ill consequences have sometimes resulted.

Uses.—In medicine it is principally employed in the production of the *subacetas*, and *emplastrum plumbi.* It has been applied to ulcers as a desiccative. A mixture, or rather compound, of litharge and quicklime, is employed to dye the hair black. The proportions vary from one part of each, to three parts of litharge and two of lime. Sometimes carbonate of lead is substituted (partially or wholly) for the litharge. The mixture is made into a paste with hot water, and applied to the hair for four or five hours. The water causes the oxide of lead and lime to unite, and form a kind of saline compound, called *plumbite of lime:* the lime is useful in removing the fatty matter of the hair, while the oxide of lead forms with the sulphur contained in the hairs a black sulphuret of lead.

Oleo-margarate of Lead, or Emplastrum Plumbi.

History and synonymes.—The compound called in the London Pharmacopœia *emplastrum plumbi*, is also termed *emplastrum lytharguri*, and formerly *diachylon plaster.* It was known to the ancients, but for an explanation of its nature we are indebted to Chevreul.

Preparation.—It is prepared by boiling litharge, olive oil, and water, over a slow fire, until the two first ingredients have combined into the consistence of a plaster.

Theory.—In this process the oil becomes saponified, and converted by the aid of the elements of water into *glycerine*, and two acids, namely, the *oleic* and *margaric* *. The glycerine remains in solution in the water, while the acids unite with the oxide of lead to form the *oleo-margarate of lead*, or the lead plaster. The water in this process serves two purposes: it moderates the heat, and facilitates the union of the acids with the oxide of lead.

Properties.—It is met with in the shops in cylindrical rolls, of a greyish yellowish-white colour, brittle when cold, but softening and ultimately fusing by heat. It is insoluble in water, and nearly so in alcohol. It has no taste, but a feeble peculiar odour.

Composition.—According to Berzelius it is to be regarded as a tribasic salt, consisting essentially of—

1 atom fatty acids (oleic and margaric),
3 atoms protoxide of lead,

So that its proper appellation would be the *tri-oleo-margarate of lead.*

Effects and uses.—This plaster is employed in surgery on account of its adhesiveness and the mildness of its local action, for it very rarely excites irritation. It is used to keep the edges of wounds together in persons with delicate skins; and, spread on calico, it forms a good *strapping* for giving support, and causing pressure, in ulcers of the leg,—a most successful mode of treating them, and for which we are indebted to Mr. Baynton.

Emplastrum resinæ.—When lead plaster is mixed with yellow resin, in the proportion of half a pound of the latter to three pounds of the former, it forms the *emplastrum resinæ* of the Pharmacopœia, and which is commonly termed *adhesive plaster.* This is employed after surgical operations (as amputations, &c.) to retain the lips of wounds in contact. It is more adhesive than lead plaster, but at the same time more irritant; and hence at times causes excoriation.

Emplastrum saponis.—The *soap plaster* (composed of lead plaster and soap) is a very mild application, used principally as a mechanical support, though it has been thought to possess discutient properties.

Carbonate of Lead.

History and synonymes.—Carbonate of lead has been known by various names, such as *psimmuthium, cerussa, magisterium plumbi, white lead*, and *subcarbonate of lead.* The process for obtaining it, described by Pliny, is similar to that now followed.

Native state.—This salt is found native (crystallized or otherwise) under the name of *white lead ore.*

Preparation.—The usual method of obtaining it is by exposing sheets of lead to the vapour of acetic acid. As no acetate is formed in this process, it is obvious the acid must undergo decomposition; but the precise nature of the change is not known. Pure carbonate of lead may be procured by adding a solution of an alkaline carbonate to a solution of the acetate of lead.

Properties.—As usually met with in commerce, it is a white powder, tasteless, insoluble in water, but soluble in a solution

* For a farther account of the theory of saponification, see MEDICAL GAZETTE, vol. xvii. pp. 323 and 678; and p. 115 of the present volume.

of caustic potash, as well as in nitric acid.

Composition.—It consists of—

1 atom protoxide lead ..	=	112
1 atom carbonic acid ..	=	22
		134

Characteristics.—It dissolves in nitric acid with effervescence; and the solution thus obtained possesses the general characters of a plumbeous solution which I have already described.

Physiological effects.—Its *local* effects are not very powerful: applied to ulcerated surfaces, it acts as a desiccative and astringent: swallowed in large quantities, it does not act as a local irritant, like the acetate. Its *constitutional* effects are similar to the other preparations of lead already described. I have before told you that it appears the carbonate more frequently produces lead colic than the acetate—a circumstance which, if true, Dr. Christison thinks, may be owing to the great obstinacy with which its impalpable powder adheres to moist membranous surfaces, and the consequent greater certainty of its ultimate absorption.

Uses.—As a dusting powder it has been employed in excoriations of children and lusty persons; but the practice is objectionable. It has also been used in the same form as a desiccative to ulcers, and to remove spongy exuberant granulations. The usual method of applying this compound externally is in the form of ointment or cerate. There is no formula for this in the London Pharmacopœia, though there is in the Pharmacopœias of Dublin and Edinburgh.

Acetate of Lead.

History and synonymes.—Raymond Lully, who lived in the thirteenth century, mentions this salt. It has been known by various appellations, such as *saccharum saturni*, and *cerussa acetata*.

Preparation.—It is prepared by dissolving carbonate of lead in acetic acid, filtering, evaporating, and crystallizing. In this process the acetic displaces the carbonic acid, which escapes in the form of gas, while the oxide contained in the carbonate, forms, with the acetic acid, the acetate of lead.

Sometimes it is prepared by digesting sheets of lead in acetic acid. This is a cheaper process.

Properties.—The primary form of the crystals of this salt is the right oblique-angled prism: their taste is sweetish and astringent: they are soluble in both water and alcohol. At 60° it dissolves in about four times its weight of water. When heated it first fuses, then gives out its water of crystallization, and is ultimately decomposed, yielding pyroacetic spirit and carbonic acid. Carbonic acid causes, in the solution, a slight precipitate of carbonate of lead.

Composition.—This salt consists of—

1 atom protoxide lead......	112
1 atom acetic acid	51
3 atoms water (9×3)	27
	180

Its formula, therefore, is—

$$\dot{P}b\,\overline{A}\,3\dot{H}$$

Characteristics.—When heated with sulphuric acid it evolves the vapour of acetic acid, showing that it is an acetate. A solution of the salt is known to contain lead by the tests already mentioned for this metal.

Physiological effects.—Applied to ulcers or mucous surfaces, it acts as an astringent and desiccative. When swallowed in large quantities it sometimes gives rise to symptoms indicative of local irritation. Its *remote* or *constitutional* effects are precisely those already described under the general head of the plumbeous preparations. Dr. A. T. Thomson thinks, that it can only give rise to colic by becoming decomposed and converted into the carbonate; and he advises, therefore, the free use of acetic acid to prevent its conversion into the carbonate.

Uses.—The acetate of lead is used both as a *local* and a *remote* agent.

(*a.*) *As a local agent*, we use it in the form of solution, and ointment or cerate; as a sedative; astringent and dessicative. Thus a *solution* of it is applied to inflamed parts as a sedative wash; or to secreting surfaces to diminish the discharge, as to the conjunctiva in ophthalmia, to the mucous lining of the urethra and vagina in gonorrhœa and gleet, and to ulcers attended with profuse secretion. The *cerate* is a useful application to excoriated surfaces, after burns, to irritable ulcers, &c.

(*b.*) *As a remote agent* we use it for various purposes; thus, to check hæmorrhage, particularly from the lungs and uterus; to diminish excessive mucous discharges, as from the lungs, from the intestinal membrane (as in cholera, diarrhœa, and dysentery), or even from the urino-genital membrane; to check colliquative sweating, and as a remedy for mercurial salivation. The sedative and astringent effects of the preparations of lead already explained, would, in fact, point out these compounds as remedies in the cases just mentioned. On the same principles it has also been proposed to lessen the secretion of pus, in extensive

abscesses attended with hectic fever. This salt has likewise been used in some affections of the nervous system, as epilepsy, tetanus, and hydrophobia.

Administration.—It is given in doses of from one to three or four grains, usually in the form of pill. In cholera it is sometimes given in combination with opium, and, though the meconate of morphia in the latter will decompose the acetate of lead, the resulting salts are not inactive. You will, however, not fail to recollect, that sulphuric aci l (as in the infusion of roses), all sulphates (as of magnesia, or soda, or alumina), phosphates (as of soda), and carbonates, are to be prohibited: the sulphates and phosphates, in fact, render it inert, the carbonates facilitate the production of lead colic.

Solution of Subacetate of Lead.

History and synonymes.—This liquid is usually known in the shops by the name of *Goulard's extract.*

Preparation.—It is prepared by dissolving two pounds of litharge in a gallon of dilute acetic acid, and boiling down to six pints. The two bodies combine, and form a solution of a subacetate of lead.

Properties.—The solution thus obtained has a slightly yellow tint, and a sweetish astringent taste.

Composition.—It consists of either the *tri* or the *diacetate* of lead, dissolved in a variable quantity of water.

3 atoms protoxide of lead	336
1 atom acetic acid	51
	387

Characteristics.—This solution is known to contain lead in solution, by the tests for this metal already described. From other plumbeous solutions it is distinguished by the copious precipitate produced when a stream of carbonic acid is passed through it—by its precipitating mucilage, and most other organic substances.

Physiological effects.—Its effects are analogous to those of the acetate and other preparations of lead. According to Dr. A. T. Thomson, it is more apt to produce lead colic than the acetate.

Uses.—It is rarely used internally, though it has been said to have cured hydrophobia. As an external application, it is employed both in the form of solution and ointment.

The *diluted solution of the subacetate of lead* of the Pharmacopœia is commonly termed *Goulard's water;* it is prepared by adding a fluid drachm of the Goulard's extract to a pint of distilled water. In the Pharmacopœia, a fluid drachm of proof spirit is added, but it is useless. If *common* water be employed, a white precipitate of the carbonate and sulphate of lead is produced. It is employed as a cold wash, and as an astringent and sedative application, in ophthalmia, and to ulcers attended with a profuse discharge.

The *ceratum plumbi compositum*, commonly called *Goulard's cerate*, contains the subacetate of lead. It is used in the same cases as the cerate of the acetate of lead already mentioned.

Iodide of Lead.

It was introduced in medicine by MM. Cottereau and Verdet de Lisle. It is sometimes termed *ioduret of lead.*

Preparation. — The readiest method of procuring it is to add a solution of the acetate of lead to a solution of the iodide of potassium, until a precipitate ceases to be formed. The yellow powder thus obtained is the iodide of lead. It may be procured in a crystalline form by dissolving in hot water; as the solution cools, crystalline scales of the iodide are deposited.

Properties.—In the crystallized state, it is in the form of beautiful golden yellow scales.

Composition.—It is composed of

1 atom iodine	126
1 atom lead	104
	130

Physiological effects.—It is a most powerful agent. In full medicinal doses, it acts as a local irritant, and produces disorder of the digestive functions. Taken internally, and used externally, it causes a reduction in size, and ultimately the disappearance of scrofulous tumors. It is said, "that of all preparations of iodine, this is the most efficacious, and promises the most prompt and constant action. It is, moreover, free from the inconvenience of creating the cutaneous inflammation which the simple iodine and hydriodates occasion."

Uses.—It has been principally employed as an internal and external agent in the treatment of ulcers and scrofulous tumors. You will find some notice of the use of it in Lugol's Essays, already referred to when speaking of iodine.

Administration.—It is given internally, in the form of pill, in doses of from a quarter of a grain to half a grain, repeated several times in the day. Dr. O'Shaughnessy says ten grain doses are easily borne, without the slightest annoyance. An *ointment* of it is made of about one drachm of the iodide to an ounce of lard or spermaceti ointment.

REPORT

ON THE

MEDICAL INSTITUTIONS OF IRELAND.

By Wm. P. Borrett, M.D.

Assistant-Commissioner for inquiring into the state of the Irish poor.

(Communicated by the Author.)

[Continued from p. 287.]

PART II.—ON THE COUNTY INFIRMARIES AND THE FEVER HOSPITALS.

County Infirmaries have been established in Ireland under 5, 45, 47, Geo. III. and various other statutes, with an especial view to the treatment of accidents, casualties, and surgical cases of all sorts. There is one infirmary for each county, and funds are provided by voluntary contributions, and by a cess levied upon the county at large, but which must not exceed 600*l.*, the largest sum allowed by act of parliament. Notwithstanding the small amount of this limit, it is chiefly by means of the cess that the infirmaries are supported; such, at least, was the case with those which I inspected. They were possessed of little or no property of any description; the subscriptions amounted only to a small sum, and the fines from the Petty Sessions, as well as the grant from the Treasury, are scarcely worth taking into account. Thus it appears that the main charge is borne by the county.

There are several points of objection to the present law, and to the practice under it, for the regulation of the infirmaries. First, as only one infirmary is contemplated by the law, or has been established for each county, without reference to its size, the provision thus made for the relief of the sick poor, whatever may be its other defects, is wholly inadequate to the wants of a large and extensive population. Secondly, as a tax is raised off the land for the support of each infirmary, and made payable throughout the county, a great portion of the expense, particularly in the large counties, falls upon persons who live in rateable districts, but at too great a distance to avail themselves of the institution; and hence the inmates of the hospitals which I visited were generally confined to the immediate neighbourhood. Either means were wanting to transport patients from a distance, or there was no subscriber in the way from whom to procure an order for the infirmary. Great inconvenience was felt under the present practice of allowing to subscribers alone the privilege of ordering admissions; nor had this restriction had the desired effect of increasing the number of those contributing to the support of the charity. Further, a subscriber's order being made absolute, the medical officer was left without any discretionary power, and he might thus be obliged to reject urgent cases, in order to make room for others of comparatively little importance, but in which the applicants were furnished with tickets: whence it sometimes occurred to those who had been at the pains of sending a poor man to the county infirmary, to be further called upon for the cost of supporting him in lodgings in the town until such time as he could be received into the hospital. In the Roscommon Infirmary, any expense thus incurred is defrayed by the institution.

Not only great expense is incurred, but great injury may result from the removing of patients, and the delay which is thereby occasioned, before remedial measures can be had recourse to, if the distance be considerable. How frequently does the chance of recovery depend upon procuring assistance at the time, and on the spot! In bad accidents, and certain cases requiring operation, life itself is risked by delay or removal.

The last, but not the least objection, which I shall here notice, is grounded upon the exclusiveness of the cases admissible into the infirmaries. I frequently met with persons labouring under disease of an acute as well as lingering character in the towns where the infirmaries are situate, who were refused admission by the existing regulations, although suffering for the want of proper treatment, which could only be had when hospital accommodation was provided. For these reasons it had become a very general opinion in those parts of the country where I went in the course of my inquiry, that it would be much more for the public benefit to establish district hospitals upon a smaller scale, and for general purposes, in situations properly selected throughout the county, in preference to any single institution, of whatever size, and however well conducted, which bore an exclusive character: for such an institution could at best effect only a local or partial good, for which it was considered hard, nay unjust, to impose a tax upon the entire county.

The town of Mallow afforded a striking exemplification of the truth of the foregoing remarks. Although possessed of a county infirmary, and favoured, it would naturally be presumed, over other places, on this account, instead of gaining by this circumstance, it seemed to be really, upon the whole, the worse off for it. In no town which I visited did the sick indigent inhabitants stand more in need of medical

aid, while, as far as the county was concerned, such cures as were undertaken at the infirmary could only be appreciable at furthest to a very limited extent in the midst of so large and populous a community.

There are four sheds placed against a wall—a mere temporary arrangement for the reception of cholera cases, low, narrow, and ill ventilated, crowded with beds touching along the sides, and barely leaving space enough to pass down the middle. Such a mean and wretched contrivance was the only kind of accommodation for the treatment of fever for the town and neighbourhood of Mallow, distinguished as the resort of numerous strangers, and the residence of an opulent gentry. The calamitous consequence was, that by far the greater number of fever cases went entirely unrelieved and unattended to, while the few which could be received into the cholera or fever sheds were placed under such disadvantageous circumstances, as very materially to diminish the chance of cure. Not only febrile affections, but all internal complaints—in fact the bulk of diseases with which humanity is afflicted—are inadmissible into the Infirmary, which is appropriated to the treatment of cases purely surgical; whence it happens that the beds are sometimes occupied by patients with old ulcers on their legs, eruptions on the skin, with ophthalmic, syphilitic, and various chronic ailments of a mild and simple character, which might be treated for the most part quite as well if they attended as externs once or twice a week at the Dispensary.

This anomaly, if so it can be termed, is not chargeable upon the medical officers appointed to the Infirmary. It is incumbent upon them to admit such cases as the above in turn, when provided with a subscriber's order, and there was no lack of attention on their part to the proper discharge of their duties. It is not, therefore, to them that I impute the least blame, but it is to the principle that I object which obtains in the management of all these establishments; for of a truth that system must be bad which goes to provide intern accommodation in cases where it might, without any injury, be dispensed with, and leaves others at the same time to perish for the very want of it.

Instead of being an infirmary for the treatment of certain forms of disease only, and these neither the most common, nor in general of the most distressing nature, it would be much more serviceable if converted into a *general hospital*, and thrown open *for the reception of medical as well as surgical cases.* Physicians and surgeons should then be alike appointed, the beds distributed between them, and all truly necessitous persons admitted, if seriously ill, even without the form of a recommendation, giving a preference always to accidents and fever cases. There need be no fear of infection, if only the proper precautions be taken—if the ventilation be good, fumigation used, and a due regard had to cleanliness. This is well known to be the case by what is seen every day in the London hospitals, where no evil arises from the admixture of fever with other cases. But if most approved of, one ward or more might be given up to those who are suffering from fever, and they might thus be kept strictly separated from the rest of the patients. In order to promote its usefulness, a Dispensary ought to be attached to each hospital, either on the ground-floor, but having no communication with the interior, or a little apart from it, as at the lodge by the entrance to the Roscommon Infirmary. The same medical officer might take the charge of this department also: or if the hospital be large, others might be appointed, whose duty it would be to make domiciliary visits to the sick poor, besides attending regularly at the Dispensary, in the way I have already recommended when treating of this class of institutions. An hospital conducted upon a plan of this description could not fail to be of real service. It would provide intern accommodation for such cases, whether surgical or medical, acute or chronic, as stood in need of it, and for such cases only: and further, instead of their having to seek recourse at a great distance, as they are often obliged to do under the present system, it would be within the reach of all persons living in the district where the rate is payable, and thus no one having a just claim to relief need go without it.

Tralee contains a fever hospital as well as a county infirmary: but upon the principle just explained, viz.—that of establishing a general hospital, instead of hospitals for the relief of poor afflicted with fever, or other particular forms of disease, which are not to be recommended except in large towns, I would suggest the propriety of consolidating the two institutions, and carrying them on together in the Fever Hospital building. This is a neat, commodious edifice, capable of containing a hundred beds, and has recently been erected at a considerable expense to the county. It is well placed, contiguous to the town, in an open plot of ground of about an acre. Thus it is exceedingly well adapted for an hospital—much more so than the Infirmary, where the accommodation only admits of 25 beds; the rooms are small, and the site not so eligible.

But on inspecting the Fever Hospital, I found that owing to the scarcity of

the funds, it was made but little use of. It contains but 20 patients, and about twice that number of beds; and such wards as were occupied presented a comfortless appearance, being almost destitute of furniture, and not kept in a neat and cleanly manner.

As a fever hospital exclusively, so large a building is not required at ordinary times, and when fever prevails epidemically, it would not of itself be sufficient. Temporary accommodation must then be provided, and a barn, house, or other empty tenement, be applied to the reception of fever cases. Ample powers are given by act of parliament (59 Geo. III.) to meet an emergency of this sort. By this statute parishes are enabled to elect Boards of Health to remove nuisances, establish hospitals, and adopt such measures for precaution and cure, as become necessary by the occurrence of the calamity. The expense of all such proceedings to be defrayed by a parochial rate. The provisions of this statute are well adapted to the exigencies of the case, if they be only acted up to, and officers of health appointed as the act directs, but which I did not find sufficiently attended to.

A stronger argument may be adduced in favour of uniting the two establishments than that which I have grounded on the fitness of the Fever Hospital building for a general hospital, and the little need there is of it for its present purpose. From a return of their expenditure, which is given in the evidence, and comparing it with the estimated expenditure for one hospital, with as many beds as the two contain together, it will be seen that a considerable saving of expense may be effected by their consolidation; at the same time the efficiency of each may be increased and secured by an improved management. Instead of electing a mere nominal committee—certain ex officio governors and subscribers, who did not attend to their duties, but left every thing to the medical officers and treasurers—an active and vigilant supervision is required for the better administration of the affairs of the two institutions. Much complaint was made of the low state of the funds, and yet it was not usual for articles to be supplied by contract, and a heavy expense was sometimes incurred, where it might certainly have been avoided. Thus in the account of the expenditure of the Fever Hospital for 1833, (furnished me at my request by the Treasurer, but not satisfactorily drawn up,) I find an item of *seventy pounds* set down for *leeches*. The number of patients, as returned in the hospital that year, was 225. In 1831, the number was 443, or nearly double, and the charge for leeches 36*l*. 10*s*. In 1832 the number was 291, and the charge 28*l*. 15*s*. The total expense for remedies for the *three* years was only 87*l*. 7*s*. 5½*d*. Upon inquiry, I learnt that the leeches were supplied by the apothecary to the institution, at a charge of *one shilling each*. The same charge was made at the Infirmary, where the average yearly cost of leeches was stated to be about 25*l*.

If leeches can be only obtained at so high a price, the obvious remedy would be to substitute cupping or other depletory measure, as I found the medical attendants of other fever hospitals were in the habit of doing. I do not mean to prefer any charge against the medical officer, but I would observe, that the fact of these leeches being supplied by the apothecary, who was allowed in some instances, if I mistake not, to prescribe himself, gives an opportunity for the imputation of bad management, or jobbing, which ought not to be permitted in the economy of a public institution.

The management of the Roscommon Infirmary was in like manner left to the medical attendant, and the acting or under treasurer. Here, however, I am happy to be able to state, that the very strictest economy was observed. Public notice was given of such articles as were required for the use of the institution, and every thing obtained upon the most reasonable terms. The medical duties were carefully performed, and great credit is due to the benevolent individual who took charge of the accounts, for the care he had bestowed upon the subject, and for the zeal he evinced in the furtherance of this, and various other charitable objects.

The other statutory provisions for the regulation of the county infirmaries refer to the *qualification of the medical officer*, and to the *amount of his salary*. The salary is fixed at a hundred pounds Irish, or 89*l*.; and no person is eligible to the appointment except he be a member of the Royal College of Physicians or Surgeons in Ireland, (7 Geo. III).

The clause containing this restriction, (invidious as it may now appear, but necessary at the time) was no doubt introduced into the act for the purpose of securing the services of a skilful and efficient surgeon to the institution. The members of the Irish College of Surgeons are at great pains and expense to acquire sound professional knowledge and experience, and are subjected to a very strict ordeal before entering upon practice; and hence they are entitled to a preference, as a general rule. Still, the reasons just assigned do not constitute sufficient ground for keeping up a species of monopoly, which is objectionable at the present day; nor is it any longer desirable

to adhere to a rule which excludes from the county infirmaries, graduates of the London, Edinburgh, and Glasgow Colleges, or other persons duly qualified, who shall have obtained a liberal professional education, and have been examined and certified accordingly in some other accredited school. It would also tend to the advancement of surgical science, and to the benefit of the public, if the number of the medical officers to each infirmary were increased, as well as the distinction in question done away with.

I have already explained, under the head of salary, in the first part of my report, the general principle which ought to be followed out in awarding pay to medical practitioners in the discharge of public duties. For services of a higher order, the rate of remuneration should be increased. Still, the infirmaries being situate in towns, where there is opportunity and field for acquiring private practice, pecuniary compensation is not so much an object to the medical attendant, as it is in the country villages, where he depends for his livelihood chiefly, if not entirely, upon the emoluments of office.

By the 47 Geo. III. grand juries were empowered to raise certain sums for the support of fever hospitals; but after the contagious fever of 1817, additional facilities were given, by advances from the government, for their erection, repayable by instalments, and authorizing grand jury presentments for sums not exceeding *double* the amount of private subscriptions. See 58 Geo. III.

Under these statutes, fever hospitals have been very generally established in the county of Cork. It was only in one or two instances that I could hear of the grand jury having shown any indisposition to grant assistance, when the expediency of the case had been fairly made out. At Bantry, however, in 1831, the clergy of the town raised a subscription of 78*l*., and offered it to the grand jury to build a fever hospital with, but the application was refused; on what ground I could not understand, since there is an extreme want of hospital accommodation in this place, which I have elsewhere pointed out. At Kilworth, owing to its vicinity to Fermoy, the like necessity does not exist; but here, after a nobleman had expended 300*l*. in building an hospital, he could not make it available for want of funds. This was owing, however, to the gentlemen of the neighbourhood refusing to subscribe, rather than to the grand jury refusing to present. In Kerry * only two fever hospitals have been established; in Roscommon none. It becomes, therefore, a question, whether their establishment should not, under certain given circumstances, be made compulsory.

The principal fever hospital in Kerry is that at Tralee, which I have already noticed. At Killarney, the funds of the hospital were in a flourishing state at the time of my visit. They had been recruited by means of contested elections for the appointment of physician, and were husbanded by the treasurer, doubtless with the best intentions, but not with the happiest effects. The furniture of the hospital was scanty, the bedding in a bad state, the pharmacy poorly supplied, and the wards in need of cleaning, painting, and repair. The salaries of the physicians were low, and the apothecary paid by a paltry stipend of 15*l*. per annum, although daily employed at the institution. There was, however, every disposition on the part of the treasurer and the gentlemen subscribing to the hospital to make such arrangements as seemed best calculated to restore it to an efficient state. Meetings of the subscribers were summoned with this view, at which the assistant commissioners were invited to attend, and several regulations passed at their suggestion.

At Youghall and Kinsale the managing officers had done all that lay in their power to render the medical charities serviceable to the public. The physicians were in the habit of seeing poor patients at the hospital and at their own houses, and attending them when called upon, putting compensation out of the question; but their meritorious services were too often frustrated from want of sufficient funds and proper intern hospital accommodation. At Baudon, a few years ago, the resident medical practitioners, five in number, offered to take charge of the hospital, but the committee declined their offer of gratuitous attendance, preferring to have a physician attached to the institution who should be a paid and responsible agent. No fault could be found with the way in which the medical duties were performed by this gentleman; still it would have facilitated the means of procuring relief if the committee had adopted the plan subsequently proposed,—which was, to allow each physician a share of the pay, and so enlist them all in the cause of the poor; but they overruled this plan also. At Fermoy and Cove there was no lack of attention on the part of the medical officers belonging to the fever hospitals; and, indeed, generally speaking, these charities, too numerous to particularize, were well conducted. In all, however, so great was the necessity felt of accommo-

* A small but very neat hospital had just been built at Cahir, through the generous aid of the landed proprietary, but it had not come into operation at the time that I inspected it.

dation for surgical cases, that either a wing was added to the hospital, or certain wards appropriated for that purpose; but it was a common remark in all these cases with medical men who did not live in its immediate vicinity, that, as far as they were concerned, there might as well be no county infirmary at all in existence.

The medical institutions at Cork are the North and South Charitable Infirmaries, the House of Recovery or Fever Hospital, the Hospital attached to the House of Industry, the Dispensary or Humane Society, and the Lunatic Asylum. From the enumeration of these establishments it would seem that the sick poor of Cork are well off for medical succour—but the fact is far otherwise. When it is stated that there are but *sixteen* beds in the aggregate for the reception of medical cases (not febrile), and less than three times that number for surgical cases and casualties of all sorts, it is plain that with such very limited means but little can be done for the alleviation and cure of disease in a city with a population of more than 100,000. This very defective provision in point of intern accommodation in the two infirmaries has contributed to the extension of pauperism in a remarkable degree. It is become the common expedient with the poor, in the absence of all other means, to apply, as paupers, to the House of Industry, where they are no sooner received than they complain of being ill, and so contrive to get passed into the hospital belonging to it. Here, however, when once admitted, they are sure of being well attended to. It was most gratifying to remark how an institution, which had sprung up under such extraordinary pressure, and was full even to excess, could be so well sustained by such slender means. Nothing could surpass the neatness and order conspicuous throughout, or the attention paid by the medical officers to the cases committed to their care and skill.

A like tribute of praise is due to the physicians and others concerned in the management of the House of Recovery: a more excellent establishment of the sort there cannot be; and it is only just to the physicians and surgeons attached to the two infirmaries to state, that they discharged their duties with ability and zeal, receiving little or no compensation for their arduous services. That the charities, however, in the cause of which they were respectively engaged, did not prosper as they might have done, even with the inadequate resources of which they were possessed, up to the date of my visit in the one instance, and in the other only till within late years, may be ascribed to the faulty if not fraudulent practices which obtained in the management, in spite of remonstrance on the part of the medical officers, and through the neglect of the governors or trustees. In proof of this I shall extract largely from the medical evidence upon the North Charitable Infirmary, and allow the facts there recorded, which were only elicited after a lengthened and searching investigation, to speak for themselves.

On referring to the book of proceedings, it appears that scarcely any regular meeting of the governors has been held for the last forty years to elect trustees according to the provisions of the Act of Incorporation of 1774; and although this act requires that the accounts should be examined every month by five trustees, they seem for many months together to have been entered in the book at the same time, and frequently in the presence of only one, and seldom more than two, trustees. Indeed, no other signature is to be found in the account-book for several years in succession than that of the late surgeon, who was also a trustee.

Having understood that a meeting of the trustees for the North Charitable Infirmary was fixed for August 5th, the assistant commissioners determined upon being there. After waiting for an hour beyond the appointed time, the son-in-law of the apothecary to the establishment made his appearance, but with this exception the meeting passed unattended. It may be taken as a specimen of the annual meetings, at which the attendance had so much fallen off, that the apothecary stated that he was desired by one of the only two gentlemen who were present on the last occasion, to reappoint the same persons as trustees for the year following. The assistant commissioners attended also at the Infirmary on August 6th, which was the day fixed for a monthly meeting; but no accounts were prepared, and no trustee present. The treasurer did not attend either this or the former meeting, although he had fixed to do so.

At present, it appears, the whole business of the charity has been allowed to pass into the hands of the apothecary, who constitutes in himself the Board of Management, and, besides being apothecary to the institution, is the druggist, steward, accountant and collector, purveyor of stores of all kinds, whether food, fuel, medicine, furniture, or clothing. He finds the Charity with everything, and on his own terms, as nothing is obtained by contract.

As apothecary he receives a salary of *52l. 12s.* per annum, but he has ceased to reside there since 1832, when the Hospital was given up for the reception of cholera cases. He has an assistant, however, at a salary of *37l.* who is provided with lodg-

ings in the establishment. This assistant apothecary, as he is termed, is a young man, and apprentice to the apothecary. He is totally incompetent to take the charge of the hospital, which is left to him in the absence of the attending medical officers, and there is no record of his appointment by the trustees or governors upon the books of the institution.

The medicines are all supplied by the apothecary, who keeps a large druggist's establishment in the city. Their cost appears to have been unreasonably high until lately, when the apothecary consented to charge the North Infirmary at the same rate as medicines were supplied by tender to the South Infirmary. On this account the bill for medicines has diminished of late years, although twice as many extern patients have been prescribed for and supplied with medicine at the hospital; and, although the number of beds has been increased by one-third since 1829, the annual expenditure is much the same as before that time. The same number of beds is, however, still maintained at even a considerably less expense at the South Charitable Infirmary.

The servants are all appointed and paid by the apothecary, and liable to be discharged at his pleasure. The number returned seems unnecessarily large for an establishment containing only thirty beds, or thereabouts. They consist of a doorkeeper, a matron, two nurses, two kitchen maids, and an assistant kitchen maid, as they are designated. It did not appear that there was any occasion for two of these servants, or if in the house, that they were occupied in the service of the Charity; and the washerwoman acknowledged that she had been employed for the last twenty years in washing for the apothecary and his family, and that articles were regularly sent from his private residence and made up at the institution, and no other work was done by her, although every thing was paid and found out of the funds of the Charity.

The system of account-keeping, if system it can be called, which is also conducted by the apothecary, reflects any thing but credit either on those who made up the accounts, or those who audited and passed them; and it is really a matter of astonishment, that a more clear, explicit, and satisfactory statement of the expenditure of the public money should never have been required by those who were appointed trustees to the Charity, for the express purpose of being guardians of the public purse. It would scarcely be supposed that the heaviest charges on the list, frequently exceeding fifty, and amounting occasionally to a hundred pounds and upwards, recurring monthly or nearly so, should be entered under the very vague and general head of "sundries." Under this head are included coals, chandlery, grocery, spirits, and repairs of all kinds, &c. &c. and on examining the stewards', or rather the apothecary's, private book, to ascertain the average annual cost of such articles, it was found that they varied in a remarkable degree; and yet they ought to have been pretty constant, seeing that the number of patients was for the most part the same. Many bills had been allowed to run on from year to year, and the charges for coals, soap, candles, grocery, &c. were most extravagant.

In the year 1832 a report was presented to the trustees by the physicians and surgeons of the Infirmary, recommending the appointment of a monthly committee, who, in conjunction with them, should provide for the internal management and economy of the hospital. They urged the necessity of establishing a regular dietary, whereby there could be a daily check upon the consumption and cost, and also suggested that all articles should be supplied by contract after public advertisement. Their recommendation was referred to a committee, who never reported at all upon it, and things were allowed to go on as before.

The only person besides the apothecary who seems to take any part in the management of the North Infirmary, is the treasurer. He acts without a salary; but he gives no security for the money placed in his hands, nor can he be said to account to the governors, as they scarcely ever hold a meeting. In 1832, a legacy of 500*l.* was left to the Charity, and an order was made by the Board to have it lodged in the Savings' Bank. This order bears the date of May 7th, 1832, but it had not been complied with in the summer of 1831, at the time of the visit of the assistant commissioners; and they were told that repeated individual applications had been made to the treasurer to have it so lodged, but without effect. It is expedient that the money should not be thus left at the entire disposal of any treasurer, as in the time of the last treasurer there seems to have been a good deal of trafficking with the funds. Various sums of money belonging to the charity had been lent to different persons for their own uses, and at different times, without, as it would seem, any order of the Board, or the sanction of the trustees. Two large sums, one 646 .3*s.* 1*d.*, and the other 369*l.* 4*s.* 7*d.* were returned as still due, together with interest which had accrued upon the latter sum to as much or even more than the original debt. And at this time there is a Chancery suit pending, in which the charity is concerned, a bill having been filed against the trustees to

recover a property mortgaged to them for a sum of money lent by them to one of their own body. If the trustees be not personally liable, the expense of litigation must fall heavily upon the funds, and if the decision prove unfavourable to the charity, it will be reduced to almost a state of insolvency.

Thus charged with debt, involved in litigation, the remnant of its property imperfectly secured, its income small and diminishing, (the number of subscribers being reduced to nearly the number of trustees appointed by the act, and being for the most part personal friends of the officers,) this institution seems to be fast approaching to a critical period, beyond which it is very doubtful whether it can contrive to exist. The establishment itself is as worn out as its resources. Only seventeen out of thirty-four beds were kept up at the time of my visit, and the furniture, sacks for straw bedding, sheets, blankets, domestic and pharmaceutical utensils, &c. whether from decay or dirt, were scarcely fit for use. Admitting that this in a great measure might be owing to the expectation of moving shortly out of the old building into the new one, still it is clear that the new Infirmary cannot by any possibility be made available for any useful purpose, unless there be a total change in the system—unless each department be remodelled, except that of the physicians and surgeons, and, above all, the Act of Incorporation be done away with, under which the North Infirmary has been mismanaged for so many years, and dwindled down into a mere family concern, while ostensibly existing as a public charity.

There is only one point to which I shall refer in the past management of the South Charitable Infirmary. It will be a much more agreeable and useful task to describe the praiseworthy manner in which it is at present conducted. The late treasurer, it appears, who continued to act even after he removed to Dublin, was in the habit of paying the debts of the institution by notes of hand or bills, and articles were declared paid, for which, in fact, the payment was not effected till some time after. This serves as an additional illustration to the instances * already given of the faulty manner in which the funds of public charities are liable to be administered, even when entrusted to persons of the highest respectability. At present the funds are very properly placed in the Savings' Bank, and thus, besides being better secured, they are made to bear interest. A further improvement would be, if they were so placed in the name of more than one individual.

* See under head 'management' in the first part of Report.

The trustees of the South Charitable Institution, (as I was informed by Drs. Woodroofe and Harvey,) anxious to diminish, as far as possible, the great disproportion of hospital accommodation to the wants of the poor of so large a city, made, in 1831, at the recommendation of the physicians and surgeons, an entire change in the management of the establishment. Since that period they have thrown open to free competition the supply of medicines, provisions, coals, and, in fact, every article which could be thus obtained on better terms. Contracts are also made every half year for particular articles when any advantage can be gained by it. They at the same time adopted the military system of diet-rolls, tabular extracts of expenditure, &c. with such modifications as were applicable to the institution. From these and other regulations they are now enabled to ascertain, at any period, not only the actual rate of gross expenditure, but also the most minute details of each article of consumption; and experience has fully warranted the confident opinion expressed by the medical officers in their recommendation, that the advantage of system and regularity thus introduced, would be still less remarkable than its economy. This will be readily seen by comparing the average outlay and amount of medical relief of two years before, and two years after, the adoption of these measures.

Admitted on the books—

In 1828	Interns 295	Externs 8558
In 1829	— 332	— 8442

Average interns 313, externs 8500, total 8813.

Average expenditure, 832*l.* 6*s.* 0½*d.*

Admitted—

In 1832	Interns 339	Externs 10,004
In 1833	— 358	— 12,248

Average interns 348, externs 11,126, total 11474.

Average expenditure, 686*l.* 6*s.* 2¼*d.*

Thus we have, on comparing the two periods, an actual saving of 145*l.* 19*s.* 9½*d.* with a mean increase of 35 interns, 2626 externs, or 2661 in the total number of patients; notwithstanding a deduction which should be made for repairs in the latter period, added to the disadvantage of another circumstance which is not taken into account—that in the two former years, the lock wards being then open, nearly one-half the diets consisted of bread and milk*.

* According to a calculation made by Dr. Harvey,—

The cost of a milk-diet was only 3⅛*d.*
— low-dict — [illegible]*d.*
— full-diet — 4*d.*

at the contract prices of the South Infirmary. In other hospitals the average cost of one diet was 5*d.*

When retrenchments upon so large a scale (which allowed the opening of additional beds) could thus be effected, by the adoption of a better system of management at the South Infirmary, it must be matter of surprise to all, as well as of reproach to the governing body of the North Infirmary, that they should persist up to the last in the old system, uninfluenced and unreclaimed by the good example set by the sister institution.

The new building for the North Infirmary has been raised by a fund of 3300*l*., derived chiefly from a legacy which was left for the promotion of some charitable object, and was applied to this purpose and added to by subscriptions. It stands upon a piece of ground, which was formerly the garden to the old infirmary, in an elevated position, but hemmed in by houses of the poorest description upon all sides. A lot of tenements in front of it, and much wanted for an approach, were offered for sale at a low price not long since, but as the trustees never held a meeting, nothing could be done in the matter. These dwellings have since been put in thorough repair, and, of course, cannot now be purchased but at a considerable additional expense.

The new hospital is substantially and neatly built, and well planned in the interior. It contains two large wards, several smaller ones, and apartments for officers and servants. It offers good accommodation for 140 patients; but when finished and paid for, the annual income will be under 500*l*.—a sum* only sufficient to provide a fourth part of the number of beds it could be made to contain. Unless, therefore, some means be found for supplying this deficiency, much money will have been expended to very little purpose, and the advantages of excellent intern accommodation, which this building is capable of affording, and of which Cork is so much in need, will be in a great measure lost to the public.

To obviate so deplorable a result, it was proposed, in the absence of better means, to unite the funds of the two infirmaries for the support of the new hospital. It was shewn that a considerable saving might be thus effected, that the number of beds might be doubled, without adding to the expenditure, by only consolidating the establishments, and an act of parliament was at length obtained for this end, at an expense of 600*l*., which was taken out of the funds for the new building. It is certainly most desirable that this plan should now be carried into full effect, if no more than sufficient funds can be raised for the support of one infirmary. It would be worse than folly in such a case to attempt to evade the Act, and to renounce the power thus afforded (after having been at so much cost and pains to obtain it,) of extending hospital accommodation to double its present amount. In the event of a union, the medical staffs of both the North and South Infirmaries might be retained, and discharge alternate duty every month, or for six months at a time, until reduced to the required number by resignation or otherwise. But who can doubt that *the two* infirmaries are indispensable? Reckoning 60 beds for the South Infirmary*, and 140 to the new North Infirmary, what are 200 beds among a population exceeding 100,000, for medical and surgical cases and casualties of all sorts, omitting fever cases, which are sent to the House of Recovery? In so large and opulent a city, considerable aid ought to be derived from private contributions. The feelings of humanity, and a due and enlightened sense of what is owing to society, must ensure the accomplishment of so useful an object. But if this resource prove unavailing, so great are the exigencies of the case that it should be done at the public expense, and a rate levied upon the town to the amount required. And should the plan of establishing district hospitals be adopted, one of them might most advantageously be placed in the city of Cork, and forty beds appropriated for this purpose at the new infirmary, the expense of which, of course, would be borne by the county. If this proposition be carried into effect for the two infirmaries, and the Fever Hospital be maintained on its present efficient footing, a great advance will be made in this place towards providing effectual medical relief for the sick poor. And it may be further increased by remodelling the Dispensary with branch stations in different parts of the city and the suburbs, so as to comprise the separate establishments at Douglas

* The annual expense of an hospital establishment, containing 140 beds, may be estimated at 1800*l*., or at most 2000*l*. Thus—

* In the South Infirmary there is at present accommodation for about this number, and it might be increased to a hundred at a small expense, if necessary.

and the Stroud Road. The officers of the Dispensary may thus be enabled to transmit into the hospitals cases of acute and severe disease, whether medical or surgical, or of febrile form, as soon as they shall be duly reported. At present there is no co-operation or understanding between the charities, and much mischief arises, together with waste of means, from the poor attending the infirmaries and dispensary at the same time, taking the physic given at each upon the calculation that if one be good, three must be better. This, Dr. Denis B. Bullen assured me, was a common practice.

The Cork Lunatic Asylum is intended for the treatment and protection of the destitute idiots and insane of the city and county of Cork, who are received upon the certificate of two magistrates*. It is under the direction of the governors of the House of Industry, but with distinct funds obtained by grand jury presentments, on the certificate of the physician (who is the chief officer of the establishment), as to the probable amount required. The expenditure of the governors is controlled by the grand juries at each assizes; but it is important to add, that the single clause of 27 George III., under which the asylum is conducted, provides no mode of check, or system of government, although it gives an unlimited power of obtaining money on presentment.

The asylum consists of 197 cells, 10 feet by 6, and of fifteen other sleeping apartments, of from 50 by 20 to 14 feet square, with eating-rooms, or day-halls, for each ward. It contained 353 patients at the time of my visit, 177 being males, and 176 females. It was stated that an excess of males invariably came from the county, and of females from the city. The annual expenditure, upon the average of the last four years, was upwards of four thousand pounds (4098*l*.†)

From the great size of the county, as well as the city, and the indiscriminate admission of all classes of the insane, the pressure of cases is always heavy, and the number constantly accumulating in the house, for which there is no vent but death: such are congenital idiots, and confirmed epileptics (of which there were as many as 88), and other incurable cases of the like kind.

Thus the institution had become crowded far beyond the proper means of accommodation. No less than forty of the inmates were huddled together, for want of room, every night into one apartment littered down with straw—a practice which had led to the most disgusting consequences. In the yards, too, by day, it was almost impossible to preserve order and quiet in such a promiscuous assemblage of persons in every stage and variety of lunacy. Neither was the want of a proper separation the chief evil; for although it cannot be denied that occupation of some kind or other is of the very first importance in the successful treatment of insanity, yet the lunatics in general were left with little or nothing to do, which could serve to engage their attention. Some sat moping about the day-rooms, and in the corners, disgusting drivelling objects, who had survived the loss of every sense; but the greater part collected in the open yards, mere idle spectators of the follies and ravings which were being enacted before them by chattering grinning idiots, or by their more violent and contumacious brethren, who, although harmless from being confined in strait waistcoats, would still be threatening and vociferating. Thus it appeared that even those which were favourable cases for a cure, were placed under circumstances which could not but militate against their recovery.

To the present physician, however, even under the existing arrangements, imperfect as they unquestionably are (which, as I have remarked, is chiefly owing to the excess of patients), the establishment is much indebted. Before his appointment, as I was informed, no kind of classification had been attempted: idiots were mixed with maniacs, and these with convalescents, to their mutual torment and danger. From the inadequacy of attendants, 80 patients out of 287 had been for months confined to their cells, many of them crippled in consequence; and male keepers were in charge of female wards. Through his exertions additional wards have been built, and an hospital for invalids was being erected at the time of my visit. A kind of fourfold distribution of the patients has also been effected, and other judicious regulations introduced for their better management and treatment. The keepers, too, had been doubled in each ward and yard, by which excitement was abated, and confinement and personal restraint dispensed with in many instances; and, at the same time, female delicacy was respected and preserved, by the exclusion of male keepers from the female wards. Something, too, had been done with the view of finding employment for the lunatic patients. The cooking, washing, and the needle work, which used to be attended to in the House of Industry, were performed in the asylum, together with painting, gardening, scouring, and cleaning; and the lunatic patients were in

* A medical certificate is not required, which appears to be a great omission.

† Further particulars are given in the medical evidence.

some cases induced to work by promising them a small gratuity to be laid out in clothes, or hoarded for them for the season of their discharge, to supply them with the means of returning to the distant parts of the extensive county. In addition, it may be stated that the greatest possible cleanliness was observable in the cells, wards, and yards, and, indeed, in every part of the establishment.

That the principles of forbearance and conciliation direct the treatment of this asylum may fairly be inferred from the little restraint which was to be witnessed, and the very few cases under confinement. One case, however, I shall particularly allude to, as a circumstance occurred during the visit of the Assistant Commissioners, which was at the time made the ground for a report prejudicial to the character of the medical and other officers belonging to the establishment. It was the case of a maniac, of a hopeless and intractable nature. Upon going to his cell, we found him with his hands tied, and his feet secured to the bedstead, crouching under the straw, with scarcely any clothes about him; and anxious to ascertain whether he had been crippled or injured in any way by the coercive measures which it became necessary to resort to from the violent and outrageous bearing of the patient, we desired his handcuffs might be removed, but the keeper was unable to loose them. He succeeded, however, after a time, by means of assistance which he had procured, and it was then found that the difficulty had arisen from the lock being stopped up with plastering off the wall, which had been driven in by the wretched maniac striking his arms against the walls of the cell (as he was constantly doing.) When released, I examined him with care, but did not detect any bruises, or marks of violence, upon the wrists or other parts of his person. Understanding, likewise, that he had been visited from time to time during his confinement, I did not consider that a case had been made out implying a want of proper attention or humanity on the part of the attendants; on the contrary, I looked upon it as an accident which might have occurred in any asylum, however well regulated*.

Some idea of the degree of success obtained by the physician since his appointment may be gathered from his reports, printed and published annually, from which it appears that the average annual admissions exceed a hundred for the last eight years; and that those cured, or so relieved as to be removed by friends, amount to two-thirds, and the deaths to one-fifth, or nearly so, of the whole number. But even if this be a very favourable result, which beyond a doubt it is, it must still be presumed that the amount of success would be further increased, if the treatment were conducted under less adverse circumstances—if the institution were less crowded, employment found for the patients, curables and incurables less blended together, and that space which is now appropriated to the safe custody of incurable lunatics were more usefully employed in the treatment of cases in which the probabilities of recovery still exist.

The physician enjoys a salary of 175*l*.; 100*l*. on account of the county, and 75*l*. for the city; but his duties are onerous,—in fact, he may be said to have the entire charge of the establishment, the moral governor, as he is called, being only a subordinate officer, and the surgeon admitted only when his particular skill is required. Whatever success, therefore, there may be (and I have shewn it is not a little, due consideration being had to all the circumstances), is fairly to be ascribed to the ability, attention, and method of cure, of the superintending physician. How far it may be requisite for him to undertake the financial and general, as well as the medical management of the asylum, I do not pretend to say; but there can be no error in placing a professional gentleman, of liberal education, at the head of the affairs of such an institution, in conformity with the principle which has of late been fully acknowledged in the treatment of mental alienation—that in all attempts to benefit and cure insane persons, they should be assigned to the care of the physician, and treated in all respects with an especial regard to cerebral disease.

In conclusion, I may observe, that the Cork Lunatic Asylum was the only establishment of the kind which it came within the scope of my instructions to visit. I cannot, therefore, offer any opinion as to the propriety of converting it into a district lunatic asylum. For information in regard to the new district asylums, I beg to refer to the joint report of my "*collaborateurs*," the late Sir David Barry and Dr. Corrie.

WM. P. BORRETT, M.D.

Queen Ann Street, Cavendish Sq.
March, 1836.

---

* The poor maniac of whom I have spoken was carried off soon after by a diarrhœa. In consequence of his death, and statements reported to have been made about him, the Lunatic Committee instituted a full inquiry into his case, taking the testimony of the different persons concerned in the management of the asylum, the perusal of which cannot fail to remove any unfavourable impression, if, indeed, such a feeling should any where exist after the explanation already given.

FURTHER OBSERVATIONS

ON

AFFECTIONS OF THE BLADDER IN PARAPLEGIA.

By Thomas Blizard Curling,
Assistant-Surgeon to the London Hospital, and Lecturer on Morbid Anatomy.

In a short paper on the Affections of the Urinary Organs, so generally observed after injuries and diseases of the spine causing Paraplegia, inserted in the Medical Gazette, for October, 1833, (vol. xiii. p. 76), I was induced to arrive at two conclusions:—1. That the morbid state of the bladder results from the loss of the natural sensibility of its mucous surface — that is to say, that being deprived of the nervous influence which it receives from the medulla spinalis, its ordinary stimulus to evacuation is lost; it is constantly subject, therefore, to the injurious effects of over-distention, the acrid properties of unhealthy urine, and the frequent introduction of a catheter, and there is, in the first instance, a deficiency of the *natural healthy* secretion necessary for its protection; so that under a combination of unfavourable circumstances, it can rarely escape disease. 2. That the alkaline condition of the urine is produced *primarily* by the morbid secretions of the bladder, and *secondarily* by the altered secretion of the urine, arising from a debilitated and irritable state of the system, or from a sympathetic affection of the kidneys.

I was not then aware that I had been in some degree anticipated in the first conclusion by Dr. Alison, and I was much gratified in finding that it was in accordance with the opinion of so eminent a physiologist.

Several cases have since come under my notice, at the London Hospital, which tend so completely to sustain the accuracy of the second, that I think they will be regarded well worthy of record.

Case I.—*Fracture of the Sixth Cervical Vertebra — Separation of the Right Sacro-Iliac Symphysis.*

Eliza Sayer, a married woman, aged 33, was admitted into the hospital, under the care of Mr. Luke, October 10, 1834, in a state of collapse; having thrown herself out of a second-story window a few hours previously. On examining the back, a crepitus was felt about the lower cervical vertebræ, and also at the sacrum. There was loss of sensation and motion in both lower extremities, and also numbness of the abdomen, chest, and arms, particularly of the left upper extremity, in which there was complete paralysis of the parts supplied by the spinal nerve. Respiration was carried on solely by the action of the diaphragm. After a few hours there was slight reaction, and it became necessary to empty the bladder by means of a catheter *.

11th.—Great pain experienced in the back; quick pulse, and hot skin. The urine was drawn off and examined about 2 p.m. It was transparent, of its natural colour and odour, and readily reddened litmus paper. In order to prevent it from accumulating in the bladder, an elastic gum catheter was retained in the urethra, both orifices being left open, so as to allow the urine to pass off as soon as it arrived at the bladder.

12th.—The dresser, on visiting her about 9 a.m., found the urine, recently received into a porringer, so highly ammoniacal as to affect his eyes when examining it. It was of a dark mahogany tint, rendered the turmeric paper brown, and restored the colour to reddened litmus paper.

15th.—Pulse quick, and weak; skin hot; tongue dry, &c. No urine having passed for some hours, the catheter was withdrawn; when it was found to be clogged with a thick tenacious mucus. On introducing a larger instrument, about three pints of turbid and highly ammoniacal urine were removed.

17th.—She was somewhat improved in her general state, and could move her arms a little better. Her urine, which possessed a strong ammoniacal odour, contained fragments of coagula and mucus of a distinctly alkaline quality. The bladder was carefully washed out by frequent injections of tepid water, until the fluid which escaped produced no action upon the reddened litmus papers. The bladder having then been completely evacuated, the patient was left for half an hour; at the end of which time, on introducing the catheter, about an ounce of urine was removed. On careful inspection, *it was found to be limpid, of its natural colour, without any ammoniacal odour, and to*

* Various particulars connected with treatment, not being essential for the object in view in detailing these cases, are omitted in the reports.

produce no change upon reddened litmus paper, but to give a slight tinge of red to the blue. The catheter was no longer retained in the bladder, but the urine was drawn off three times in the twenty-four hours.

22d.—She was much weaker, and suffered considerably from dyspnœa. Her urine was still highly alkalescent, and contained a large quantity of muco-purulent matter, which adhered slightly to the bottom of the chamber utensil. The bladder was directed to be washed out three or four times in the course of the day.

29th.—She had improved somewhat in strength during the last week, and ate her diet, consisting of a mutton-chop, with wine and porter. *Her urine was of its natural colour, without any offensive odour, and it reddened the litmus paper slightly.* The injections were discontinued.

November 1st.—She was seized with a kind of fit, during which she was nearly suffocated. It lasted about an hour, and left her weak, and with great dyspnœa. Urine ammoniacal.

From this time she sank gradually, and died November 7th.

Inspection, twelve hours after death.—A fracture traversing the body of the sixth cervical vertebra, the spinous process being completely broken off. No part of the bone depressed into the spinal canal. Medulla spinalis at the seat of the fracture softened, its membranes highly injected, and the theca adherent to the ligamentum posticum. A separation of the right sacro-iliac symphysis, connected with which there was a small abscess that had made its way under the peritoneum to the side of the bladder. Coats of the bladder thickened, its mucous lining congested, and of a slate colour; and at the lower and posterior parts there were several ulcers, about a quarter of an inch in diameter, which had extended through the mucous and muscular coats. *Kidneys and ureters perfectly healthy.* Cysts connected with the ovaries. An extensive slough over the sacrum*. Lungs congested.

Case II.—*Fracture of the Spine about the last Dorsal Vertebra.*

James Mulvarney, ætat. 50, a ballast-heaver, with muscles well developed, was brought into the London Hospital on the morning of June 8, 1835, having met with an accident by falling down a ship's hold, a distance of twelve feet, about an hour before. He was nearly insensible when admitted, but would answer questions if aroused. He was totally unable to move his lower extremities, but had not lost sensation. There was considerable ecchymosis at the lower part of the back, and a distinct depression and crepitus were felt about the last dorsal vertebra. He recovered himself towards evening, when he was bled. He was able to pass his water, but his fæces passed involuntarily for a few days. Considerable febrile excitement ensued, but it was checked by appropriate treatment. The urine at first became high-coloured and somewhat clouded with mucus, but, after a few days, returned to its natural state. *It was acid throughout.* No sores on the nates.

July 25th.—He was still unable to move the lower extremities, although sensation remained unimpaired. The back, in the first instance, had been largely leeched, and he had subsequently taken mercury until the mouth became so e, but without relieving the paralysis. He continued in the hospital for several months, during which time issues were made in the back, and electricity and other measures resorted to, without much benefit. His bowels continued very costive, and constantly required some purgative in order to enable them to perform their functions.

Discharged January 21, 1836; the muscles of the thighs and legs being somewhat atrophied, and with no power over the left lower extremity, and but very little over the right.

Case III.—*Fracture of the Twelfth Dorsal Vertebra.*

John Johnson, aged 25, an engineer, and a robust healthy man, was brought into the hospital, about 1 P.M., June 19, 1835, having been injured by the slide valve of a steam-engine, consisting of about a hundred weight of iron, falling upon the lower part of his back. He was in a state of collapse, and had lost both the power of moving and sensation in the lower extemities. There was slight priapism, and he complained of great pain about the twelfth dorsal vertebra; which, upon examination, was found to be considerably depressed below the level of the eleventh. In

* She was placed upon an hydrostatic bed on the second day after the accident.

order to remove the displacement, Mr. Luke, under whose care the patient was admitted, directed the shoulders to be fixed, and gradual extension to be made from the feet. During its performance, the man remarked that he felt as if something had slipped into its place. The depression was removed; he expressed himself in some degree relieved from the pain, and the priapism slowly subsided. His urine was drawn off, and, being tested with litmus paper, was found to be acid. He was placed upon a water bed, and in the evening his back was leeched. Urine directed to be drawn off three or four times in the twenty-four hours.

20th.—Had passed a good night, and was free from pain. Feverish, and urine high-coloured and acid.

21st.—Complained of a smarting pain in the course of the anterior crural nerves, especially of the right. Urine turbid, of a mahogany tint, but slightly acid.

22d.—In the morning his urine was loaded with mucus, but it reddened the litmus paper very slightly. In the evening it was decidedly alkaline, instantly restoring the colour to the reddened litmus paper, and possessing a strong ammoniacal odour.

24th.—He felt low and feeble. Urine turbid, and highly ammoniacal. Pain experienced in the hypogastric region if the water is not drawn off frequently. A small quantity dribbled from the urethra. Prickling pains felt along the lower extremities.

29th.—Health a little improved. On introducing a catheter, *the urine first removed was observed to be perfectly clear and acid; but that which escaped afterwards, being received into a separate utensil, was found to be turbid, and did not affect the blue litmus paper.* The urine continued to dribble from the urethra, but the bladder was never wholly emptied. The insensible glans penis, prepuce, and scrotum, were much excoriated. The prickling pains in the limbs were much increased, and the skin was so sensitive that he could scarcely bear the bed-clothes upon them.

> Ordered the decoction of Pareira Brava, with ten minims of Nitric Acid, three times a day.

July 28th.—Was weaker, and emaciated. The integuments over the sacrum had sloughed. Urine limpid, but ammoniacal. Having caught cold, some antimonial medicine was substituted for the pareira brava and nitric acid. On the following day, his urine was excessively turbid, but on resuming the acid medicine a day or two afterwards, it again became clear, although alkalescent. His water dribbles away as soon as a small quantity is collected in the bladder.

August 30th.—Improved in health, and sits up for a short time daily. The bladder appearing distended, a catheter was introduced, when some calculous matter was felt, which, having been disturbed by the catheter, a small quantity of the phosphate of lime, of the consistence of mortar, passed away with his water in the course of the afternoon.

September 19th.—The sore on the nates had extended, and he was much weaker. The bladder was washed out for several days with tepid water, but the urine still continuing ammoniacal, some nitric acid was injected, in the proportion of a minim and a half to an ounce of water. As, however, he experienced considerable uneasiness after it, and was unable to rest the following night, and the urine which passed during the next day having been bloody, the injection of acid was not repeated.

24th. — Appetite diminished, much weaker, and extremely emaciated. The urine being exceedingly turbid and offensive, the bladder was again injected with warm water once daily; and after a few days it became clear, and was but slightly alkalescent.

Oct. 12th. — Very feeble; sloughing of the integuments on the outer part of the left leg, where it rested upon the bed. Sore on the nates increased; pain experienced in the lumbar and iliac regions, which were tender to pressure. It was slightly relieved by the application of a few leeches. Urine ammoniacal, and much loaded with mucus.

From this time he gradually got weaker, but lingered on till the 4th of November, when he died.

Inspection, 30 hours after death.—The body extremely emaciated, especially the lower extremities, which were atrophied in a greater degree than I ever remarked in the most lingering cases of phthisis. Miliary tubercles in a state of softening, thickly studded throughout the lungs; heart natural. Bladder contracted and thickened, its mucous coat covered with numerous tubercles of lymph. Ureters much thickened, and their mucous lining in-

jected, and also coated with lymph. Kidneys highly injected, with the mucous membrane of its pelvis thickened, and studded with granular projections of lymph. Some loose calculous matter in the kidneys, and in the ureters. The fracture had traversed the body of the twelfth dorsal vertebra, close to its upper articulating surface. It was displaced so as nearly to obliterate the vertebral canal, and the intervertebral substance between the eleventh and twelfth was entirely wanting. A portion of bone was also detached from the body, in front; union between the broken bones tolerably firm, although partly ligamentous. Medulla spinalis at the seat of injury in a state of ramollissement. I was desirous of examining the nerves, muscles, and bones of the lower extremities, but was prevented by the interference of the friends of the deceased.

Case IV.—*Fracture of the skull, and of the seventh cervical vertebra.*

John Reed, a stout man, aged 45, was admitted into the hospital under the care of Mr. Scott, Sept. 28th, 1835, having met with an accident in the London Docks about two hours previously, by falling from a height of 12 feet on the deck of a vessel. He was partially insensible, and in a state of great prostration, but soon revived, and complained of a violent pain in his neck, which was much increased by the slightest motion. On examining the neck, the spinal process of the seventh cervical vertebra was found depressed, and it produced a crepitus when moved. Respiration performed solely by the action of the diaphragm. Loss both of sensation and motion in the lower extremities. Fingers felt numbed, but he was able to move his arms. There was considerable priapism, but it soon subsided.

29th.—Quite sensible, and complained of severe pain in the neck. His fæces passed involuntarily, and it was necessary to relieve his bladder by means of a catheter: but very little urine was secreted—scarcely half a pint in twenty-four hours.

Oct. 1st. — Feverish, with a quick pulse, and much inclined to dose. Urine scanty in quantity, high-coloured but acid.

3d, 2 P. M.—Still feverish; urine of a deep mahogany tint and acid, with a small quantity of mucus, which subsided in a cloud towards the bottom of the chamber utensil.

9 P. M.—Urine decidedly ammoniacal, instantly restoring the colour to reddened litmus paper.

4th.—Evidently much worse. Considerable dyspnœa and a feeble pulse. Towards the afternoon he became comatose, his breathing stertorous, and his pupils did not act to the stimulus of light.

Died at 7 P. M.

Inspection, eighteen hours after death.—Cutaneous vessels of the head and neck turgid. A fracture traversing the squamous part of the right temporal bone, and of the parietal, running partly in the groove for the spinous artery. Membranes of the brain much congested. Blood extravasated beneath the pia mater on various parts of the cerebral surface, and about an ounce and a half effused under the dura mater at the part corresponding with the fracture. A small quantity of blood extravasated in the cortical structure of the brain, at the under surface of the middle lobe on the right side. A fracture of the cartilaginous junction of the upper bone of the sternum with the middle. Slight extravasation in the anterior mediastinum. Sanguineous congestion of the lungs. A fracture extending through the body of the seventh cervical vertebra, with such displacement of the upper part of the bone forwards as to compress the medulla. Pia mater investing the cord at the seat of the injury unusually injected, and the medulla itself softened. Kidneys healthy. *A small quantity of urine remaining in them distinctly acid. The bladder full of urine highly ammoniacal.* It presented, at the upper and under part, a light red colour, but around the sides it had a dark brown or deep chocolate hue. On stripping off portions of the mucous membrane, this remarkable appearance was found to arise from a diffused extravasation of blood.

Case V.—*Fracture of the eighth dorsal vertebra.*

Samual Small, æt. 36, a labourer, admitted Jan. 28th, 1836, under the care of Mr. Scott, having met with the following accident. Whilst walking along a street and stooping somewhat forwards, he was suddenly knocked down by a sack of coffee (about 3 cwt.) falling upon his back from a crane to which it had been suspended at a height of

fifty feet. He complained of great pain in his back and chest, and had lost all sensation in, and power of moving, the lower extremities. There was priapism, and a distinct depression about the lower dorsal vertebræ

29th.—Considerable constitutional irritation; stomach rejected every thing that was swallowed. Great pain experienced in the back; fæces passed involuntarily, and not more than three ounces of pale-coloured acid urine were drawn off in the course of twenty-four hours.

31st.—Stomach still continued very irritable; less fever, but pulse feeble and intermittent; rather more urine secreted.

Feb. 3d.—Irritability of the stomach diminished; pulse quick; abdomen tense, tympanitic, and painful on pressure; urine abundant in quantity, of its natural colour, and acid.

14th.—Diarrhœa and vomiting; abdomen tympanitic and tender; pulse full and quick; countenance anxious; urine acid.

15th.—Urine high-coloured, but acid; stomach rejects every thing.

16th.—In every respect worse; constant restlessness; countenance anxious; respiration difficult; bowels relaxed; urine alkaline.

17th. — Gradually getting worse; urine highly ammoniacal.

Died on the 19th.

Inspection, thirty hours after death.—Lungs in a state of engouement, and the pleuritic surfaces behind connected by recent adhesions. Blood extravasated in the posterior mediastinum, and in the subserous cellular tissue on each side of the spine. A fracture through the body of the eighth dorsal vertebra, with displacement of the inferior portion backwards, so as to compress the medulla. Spinal cord at the seat of injury softened, and infiltrated with purulent matter. Theca around highly inflamed. Peritoneum generally somewhat injected. Cæcum and sigmoid flexure of the colon connected to the fundus of the bladder by recently effused lymph. Bladder apparently much distended, mounting up considerably above the pubes. On opening it less urine found than was expected, the organ being displaced forwards and upwards. Considerable turgescence of the vessels of its mucous coat, which was partially coated with loose lymph. Urine very ammoniacal and turbid. Between the right side of the bladder and the cæcum and commencement of the colon there were about four ounces of pus, contained in a cyst of loose lymph, which appeared to be giving way or ulcerating towards the colon. At the part of the colon corresponding with this spot there was a congested state of the vessels, with slight extravasation of blood. Both ureters and pelves of the kidneys inflamed and distended with purulent and ammoniacal urine, more especially the right. Structure of the kidneys unusually vascular, friable, and readily broken down with the fingers. Abundant suppuration between the bladder and rectum, and throughout the loose cellular tissue of the pelvis, which accounted for the displacement of the bladder.

These are not the only cases that I could detail in illustration of the nature of the lesions of the urinary organs in paraplegia after fractures of the spine, but they are, I apprehend, amply sufficient to indicate the original seat of disease. In my former communications I argued, that the alkaline property of the urine, in these cases, is originally dependent upon the diseased state of the bladder, as in ordinary inflammation of this organ, where the mucus, which is abundantly secreted, being highly alkalescent the urine is decomposed, or acquires similar properties. I stated, however, as a secondary cause, that in consequence of the febrile excitement of the system, and the debility which takes place after these severe injuries, as well as of the extension of inflammation along the mucous lining of the ureters, the kidneys also become liable to secrete alkaline urine; in which case, as the secretion is more stimulating than healthy urine, it tends to keep up and aggravate the inflammation already existing in its unprotected mucous membrane. I endeavoured further to show, that the observations of Mr. Smith, of St. Mary's Cray, Kent*, which tended to a different conclusion, by no means warranted the inferences that were drawn from them.

In Case I., the patient being a female, an excellent opportunity was afforded for performing an experiment similar to that described by Mr. Smith; but the result was widely different. Thus it appeared, that the urine was secreted in

* Med. Gaz. vol. ix. p. 661.

its natural acid state, although it was voided ammoniacal, clearly showing that it must have acquired this property in its passage through the bladder. In order, however, to clear up any doubt that might exist in this experiment, as to the fluid evacuated at the termination of half an hour having arrived from the kidneys in the interval, this fluid as well as the water last removed after repeated injections, and which was found to produce no action upon the reddened litmus paper, were kept for 44 hours, at the end of which time the properties of the latter were found to be unchanged. The former, however, had become decomposed, and was strongly ammoniacal. In Case III. it appears that on the tenth day after the accident the urine was secreted in its natural condition, although the mucus with which it was loaded was alkalescent, but at a subsequent period, when the bladder was more affected, and when probably the kidneys had began to participate in the disease, the urine was likewise alkaline. In this case, the patient having survived for nearly five months, the inflammation extended from the mucous membrane of the bladder along the uterus to the kidneys, the pelves of which were in part coated with lymph. In Case IV., however, where the injuries were of so severe a nature as to occasion death so early as on the sixth day after the accident, the bladder only became affected, the urine in it having been highly ammoniacal; whereas the kidneys were healthy in structure, and the little urine contained in them distinctly acid.

That the alkaline property of the urine in these cases is not wholly attributable to its being retained a sufficient time to undergo decomposition, as contended by Dr. Burne *, in his notice of my former remarks on this subject, is satisfactorily shewn by the first case, in which care was taken that the urine should dribble away as it arrived from the kidneys. I might adduce many objections to this opinion, but will confine myself to one. I have observed, in two or three cases of retention of urine from enlargement of the prostate gland, in which the urine was drawn off twice in the course of the day, that although the bladder was seldom, if ever, completely evacuated, the urine was acid. But on retaining an elastic gum catheter in the bladder, although the organ was relieved more frequently than before, considerable irritation was excited, and the urine was rendered turbid and ammoniacal; for it appeared that the bladder became intolerant of the additional irritation caused by the constant pressure of the catheter; inflammation, therefore, was set up, alkaline mucus was abundantly secreted, and the urine underwent decomposition. In these instances, then, it is perfectly clear that the ammoniacal condition of the urine was not owing to mere detention.

In the case of paraplegia related by Dr. Burne, the point of the catheter, although the instrument was not retained in the bladder, appears to have excited ulceration in the mucous membrane in three separate places. The same process was found to have been set up in Case I., in which an elastic gum catheter was kept in the bladder for seven days. I should never in future adopt this proceeding, the frequent introduction of an instrument being far preferable; since when deprived of sensibility, this organ is so ill able to resist injurious impressions.

Mr. Stanley, in an interesting paper contained in the 18th volume of the Transactions of the Royal Medical and Chirurgical Society, has adopted the views of Mr. Smith, although, in the two cases of injured spine which he quotes, the bladder appears to have been the chief, if not the sole seat of disease. Mr. Stanley seems to imagine, that after injuries of the spine the affections of the urinary organs are owing to irritation communicated from the spinal cord to the kidneys through the medium of the nerves passing from the lumbar ganglia to the renal plexus. That such may be the case in particular instances, I would not venture to question; but that the lesions of these organs, in cases of paraplegia from injury to the spinal cord, generally arise in this way, I think the facts stated in this paper tend greatly to disprove. In Case II., in which the spinal cord was evidently much injured, as evinced by the total loss of the power of moving the lower extremities, there was no affection whatever of the urinary organs; whereas in no case that I have hitherto met with, where sensation was impaired, have they escaped disease.

The means which I believe will be found of most service in these cases, are, in the first instance, the frequent

* Med. Gaz. vol. xiii. p. 353.

evacuation of the bladder by the repeated introduction of an elastic catheter, and afterwards, when the urine is rendered alkaline, the internal administration of acid medicines, and the injection of the bladder with tepid water. The relief afforded by the latter proceeding was well marked in Cases I. and III.

Case V. is adduced as shewing the extensive disorganization which sometimes takes place even in a short time; for there was no evidence of urinary disease until within four days before death. But besides the changes already alluded to, these cases afford many other interesting points for consideration in the disturbance in the functions of different organs—as the torpid state of the bowels in Case II.; the diminished secretion of urine for some days after the accident in Cases IV. and V.; and the very irritable state of the stomach in Case V., in which the eighth dorsal vertebra was the seat of fracture. There is also one circumstance connected with Cases II. and III. which should not pass without notice. Thus it is supposed that a direct connexion subsists between nutrition and the due supply of nervous influence. Now, these patients were admitted into the hospital within a few days of each other, and both, at the time of the accident, were in excellent health, and had their muscles well developed. At the end of four months, however, there was a remarkable difference in the extent of atrophy which the inferior extremities had suffered in the two cases. In Case II., in which sensation was unimpaired, there was undoubtedly a decided alteration in the condition of the muscles, yet the degree of atrophy which they had undergone bore no comparison to that remarked in the wasted and attenuated limbs of the other, which had been deprived both of sensation and of muscular power.

Case IV. is also interesting, as an example of a severe injury of the head, unaccompanied by any decided cerebral symptoms for several days afterwards.

Having alluded to the valuable observations by Mr. Stanley, on irritation of the spinal cord and its nerves, it may be interesting to mention the particulars of a case of irritable bladder, very analogous to the case of Charlotte Sepping, described by Mr. Stanley, in which I was induced to adopt the same plan of treatment, and certainly with equal benefit.

Irritable Bladder.

Ellen Molay, an Irishwoman, aged 27, applied at the London Hospital for relief as an out-patient, at the commencement of September, 1833. She was suffering from extreme irritability of the bladder, being obliged to pass her water every half hour or hour, the act being attended with the most distressing sensations internally, described by her as bearing-down pains. Her urine was acid, high-coloured, and by no means abundant. It had been coming on gradually for about a month; it deprived her of rest at night, her health was greatly impaired, and she was so weak as scarcely to be able to walk to the hospital. The carbonate of soda, carbonate of iron, uva ursi, liquor potassæ, narcotics, cathartics, opiate enemata, pareira brava, and every kind of medicine likely to be of service, were tried, without producing the slightest relief.

Feb. 24th, 1834.—I directed an issue to be made on each side of the lumbar vertebræ, and the decoction of bark, with carbonate of soda.

March 12th.—Had been gradually improving from the time that the issues had been made. Made water much less frequently, was able to rest at night, and her general health greatly improved.

19th.—She was not so well, the irritability of the bladder and uneasy sensations having increased since her last visit. On examining the issues I found that they were partly closed up, and that there was very little discharge from them. They were ordered to be dressed with peas which had been macerated in a saturated solution of the sulphate of copper.

April 2d. — Greatly improved in health, quite free from pain, and not disturbed in the night oftener than four or five times. A free discharge from the issues.

June 21st.—Health completely re-established; seldom disturbed oftener than twice during the night. The issues had closed about four days ago.

July 12th.—Discharged cured.

St. Helen's Place,
May 13, 1836.

CONTRIBUTIONS TO THE DIAGNOSIS OF THORACIC DISEASE.

NO. IV.

By Charles Cowan, M.D. E. & P.

ON THE EXPIRATION.

Expiration — How produced — How modified by Disease—Its importance in the early Diagnosis of Tubercles.

My attention was first directed to the study of the different modifications of the *expiration*, both in health and disease, by the observations of Dr. Jackson, in the wards of La Pitié, who strongly insisted upon its utility as an early and valuable indication of increased density of the pulmonary parenchyma. In the writings of Laennec, Andral, Piorry, Williams, Raciborski, and others, the subject has not met with any special consideration; and since subsequent experience has satisfied me that it is neither destitute of utility or importance, perhaps the following remarks will not be unacceptable to those who feel that auscultation has still its difficulties and uncertainties to encounter.

If we listen to the respiration of an adult and healthy chest, beginning at the trachea, and following its subdivisions until we arrive over the vesicular structure of the lung, we find that the ingress and egress of air are in the upper portions of the tube distinctly audible, and that they produce sounds nearly, if not exactly, similar to each other. In proportion as the bronchi become smaller, more numerous, and surrounded with the pulmonary parenchyma, the respiration gradually predominates, and over the deep vesicular portions of the lung it is alone heard. To an attentive ear, the period of expiration is, however, in the majority of cases, not wholly without sound, but the murmur is distant, deep-seated, very feeble, comparatively short in duration, appearing to originate round the root of the lung in the larger bronchi, and evidently not occupying the same locality as the inspiration. In some individuals the expiration is not at all heard, while in others it is more distinct; though in no instance, where disease is absent, can it be at all confounded with the inspiratory murmur. We have found it occasionally rather more distinct in children than in adults; but even here it is not unfrequently absent, and does not at all necessarily accompany puerile respiration.

Laennec, in his description of the natural respiration, seems to have overlooked the distinction we are insisting upon; for he says, "if we apply the stethoscope to the healthy chest, we hear, during *inspiration and expiration*, a slight but very distinct murmur, indicating the penetration and expulsion of air in the pulmonary tissue *; thus evidently implying the similarity of both sounds, or at least omitting to point out either the utility or possibility of distinguishing them. Our preceding remarks prove that we consider this description of natural respiration essentially incorrect; and we hope to point out, in the course of the following observations, that the examination of the phenomena of expiration, apart from those of inspiration, cannot be regarded as a useless refinement, but as multiplying the elements of accurate diagnosis.

It may very naturally be asked, how is it that the entrance of the air into the lung is so distinctly heard, while its passage outwards is almost inaudible? This fact, we think, must chiefly be explained by reference to the elasticity of the lung itself, which has been so ably insisted upon by Magendie, and proved by that sagacious observer to play so important a part in the phenomena of natural and morbid respiration.

If we inflate a recent healthy lung, and leave the trachea unobstructed, the elasticity of the pulmonary tissue will rapidly, and almost entirely, expel the contained air, the organ collapsing upon itself, and diminishing to perhaps four-fifths of its volume when distended. The power with which the air is expelled is considerable, and the lung is emptied far more suddenly and abruptly than is the case in natural expiration. The force and rapidity of the phenomenon is in fact such, that it is impossible not to feel that the expiration must be much more dependent on this property of the lung, than on either the contraction of the muscles or elasticity of the

---

* Vol. i. p. 46; 3d edition.

ribs and cartilages. Indeed, the collapse of the healthy lung is checked, both in its rapidity and amount, by the construction of the thorax, the cavity of which can never diminish to the same extent as the lung itself is capable of doing; while the complete collapse of the latter is arrested by the pressure of the atmosphere from without. The lung, therefore, at the close of expiration, is in a state of incomplete collapse, its elasticity continuing active, but incapable of still further diminishing its volume, because this could not be effected without a vacuum being produced in the chest. The truth of this remark is illustrated by the tense and arched state of the diaphragm after death.

In healthy expiration, therefore, it is the retreat of the lung upon itself which principally expels the inspired air; and the elastic integrity of the organ is consequently highly important for the proper performance of the respiratory function. Why the passage of the air outwards should be almost inaudible when compared with the respiratory murmur, may, we think, be explained by reference to the physical conditions above alluded to. The pulmonary vesicles individually contract upon the air which distends them, forcing it into the bronchial ramifications, where it successively accumulates and acquires in the larger tubes an increase of volume and rapidity, which, through the very imperfect conducting medium of the healthy pulmonary tissue, gives rise to the feeble and distant sound characteristic of the expiratory murmur. The phenomenon is, in some respects, similar to the circulation from the capillaries into the large venous trunks; the rapidity of the blood's progress in the veins being the accumulated result of its passage in the numerous smaller channels with which they communicate.

The normal degrees of intensity of the expiratory murmur may depend on the variations which, no doubt, exist in the natural elasticity of the lungs of different individuals. If this property is feeble, all other conditions remaining the same, the expiration is slower, and no perceptible sound is produced. If, on the contrary, the elasticity is considerable, the expiratory murmur is also augmented. It should be remembered, the expired air finds but a very slight obstacle to its progress from the vesicles into the smaller bronchial ramifications, since this is effected by the spontaneous obliteration of the spaces it previously occupied, the lung itself accompanying the retreating air; but the volume of the larger tubes being increasingly disproportionate to the aggregate area of the pulmonary vesicles, and the elasticity of the lung being principally seated in its parenchymatous portions, which collapse around the larger and less yielding tubes, we can easily perceive that both the volume and rapidity of the air in the latter must be increased, and thus satisfactorily account for the nature and locality of the expiratory sound. During *inspiration*, on the contrary, the air has to overcome the resistance of the lung; it must forcibly distend the elastic vesicles, and this rough species of contact is one of the immediate causes of the inspiratory murmur.

We have not, in the preceding observations, complicated the subject by referring to the muscular contractility of the lung, which is undoubtedly liable to numerous variations, and must not unfrequently modify the character of the respiratory sounds. We have no means of accurately testing the amount of its influence, but do not conceive, that, within the limits of health, it would give rise, in regard to the expiration, to other considerations than those we have devoted to the simple phenomenon of elasticity.

Let us now examine the effects of *disease* upon the expiration. It is evident, that when the particular property of the lung we are now considering is seriously impaired, expiration must, in proportion, depend on the expiratory muscles, aided by the elasticity of the ribs and cartilages. Under these circumstances, the thoracic parietes collapse upon a distended, instead of following a retreating lung; and the air is expelled by mechanical pressure upon the pleural surface, instead of by the proper elasticity of the pulmonary tissue itself. As a consequence of this, the expiration is incomplete; the diminution of the thoracic cavity being to a certain extent impeded, rather than aided, by the condition of the lung, and because the diaphragm would have no tendency to mount upwards but what resulted from the pressure of the abdominal viscera upon its concave surface.

The inspiration must also be equally diminished, and a considerable portion of the base of the lungs be comparatively motionless. The organ would become, physically and functionally, unequally active, the respiration being most complete in those parts which corresponded to the more elastic regions of the chest; and to the ear there would be proportionate variations in the intensity of the respiratory murmur.

A second result of the condition we are describing, *is permanent enlargement* of the thorax, in consequence of the increased efforts made by the inspiratory muscles to introduce a sufficient quantity of air, over and above what remains after the very imperfect expiration. This unnatural distention inordinately expands the pulmonary tissue, and either rarifies the lung by destroying its vesicular structure, or (what is more common) produces hypertrophied enlargement of the organ. The increased size of the thorax depends, therefore, on the great activity of the inspiratory muscles, and the enlargement of the lung can only be regarded as a secondary consequence of the former. Dr. Stokes, in his interesting paper on Vesicular Emphysæma, published in the Dublin Journal for March, 1836, lays, in our opinion, much too great stress upon the hypertrophy of the lung, as a *cause* of enlarged thorax: we think it is but rarely the first link in the chain, but in general originates in some diminution of the pulmonary elasticity, and is directly the result of the inspiratory muscles becoming, in consequence, unusually active.

If we suppose the lung not to be morbidly affected in any other respect than by its diminished elasticity (which is seldom the case), auscultation would discover nothing more than very feeble or inaudible inspiration, and probably no expiratory murmur whatever. But should the smaller bronchi be obstructed by viscid mucus or thickened membranes, a sibilant wheezing would be detected during the expiration; the current of air being unnaturally accelerated, in consequence of the normal proportion between the vesicles and smaller tubes being destroyed. This is not unfrequently the case in simple bronchitis, which, by rendering the entrance of air more difficult, weakens or annihilates the inspiratory murmur, while it produces the expiratory wheezing; and when seated in the smaller tubes, we are inclined to think, also temporarily diminishes the pulmonary elasticity. We have also observed, that in certain cases of emphysema, where the elasticity is wholly destroyed, that the subsidence of the parietes upon the spongy surface of the lung after a deep inspiration, combined with the generally more or less obstructed state of the smaller bronchi, produces a superficial, though feeble, murmur, not always easy to distinguish from the effect of inspiration itself.

The expiration, therefore, with the exception of the last instance, is either inaudible or diminished, where the pulmonary structure is rarer than natural; or characterized by numerous bronchi depending on the diminished calibre of the bronchial ramifications.

Let us now examine the effect of *increased density* of the lung upon the expiration. When hepatization has taken place, the well-known effect of bronchial respiration is the consequence, and where, in addition to this, a cavity is formed, cavernous or tracheal respiration is produced. Both these sounds are familiar to auscultators, and are satisfactorily explained by the increased conducting power of the lung. We need only remark, at the present moment, that they are usually double, *i. e.* heard during expiration as well as inspiration, as is naturally the case in the trachea and larger bronchi.

But there are many intermediate changes of density between a healthy and hepatized lung, more especially in the progress of tubercular disease; and we have found the study of the expiration, under these circumstances, of the greatest value in aiding, and sometimes for forming, our diagnosis. In cases of scanty miliary tubercular deposit, scattered through an otherwise healthy parenchyma, we believe it will be more easy to estimate the changes occurring in the expiration than in the inspiration, and, in several instances, the former has presented decided modifications, when neither the inspiration or percussion were appreciably affected. Besides, the inspiratory murmur may be locally stronger and weaker from a variety of causes, whereas a decided increase in the expiratory sound, almost always depends on *increased density* of the lung; and, by careful comparative examination, very slight deviations from the

healthy state may be detected. When studying the expiration, it is not merely the amount of sound that we seek to appreciate, but its being more or less superficial, and appearing to occupy the same locality as the inspiration; of which it appears at first more like a distant echo, but, with the progress of the morbid changes, ultimately becomes a repetition. There are cases, where one or more of the larger bronchi are suffering from compression, where the expiration is increased, though the density of the lung is unaffected; but, under these circumstances, the sound is distant, and can be traced to its point of origin. Occasionally the expiration is more distinct than the inspiration, and without attention it may be, and no doubt has often been, mistaken for the latter; we should of course be guided by determining its coincidence with the elevation or depression of the ribs.

The reason of our attaching so much importance to this stethoscopic sign, is its applicability to an early period of disease, when accurate diagnosis is at once so desirable and so difficult. Our knowledge of the precise portions of the lung, where tubercles are almost invariably first deposited, enables us to appreciate slight local changes in the character of the respiration, which, with a less certain pathology, would be of little practical utility, but, from the uniformity of the morbid alterations, the attention of auscultators cannot be too much fixed upon all those physical indications, however minute, which characterise the earlier stages of tubercular disease.

We believe that auscultation, as a means of acquiring this very desirable knowledge, is in general underrated, and that its utility is more frequently limited by inadequate study and want of attention to minutiæ, than by any inherent deficiencies;—in short, the auscultator is more to be blamed than his instrument. We therefore direct the attention of stethoscopists to the examination of the expiration in general, but especially with reference to the earlier stages of tubercular disease, believing that familiarity with its modifications will not only, in conjunction with other data, assist our diagnosis, but, in some instances, mainly contribute to its formation.

The effects of disease upon the invisible physical qualities of our tissues, is an interesting but comparatively unexplored subject of research. Their density, cohesion, and elasticity, are, no doubt, constantly varying with the nutritive and nervous functions, but in no organ would any physical disability be more sensibly felt than in the lungs, both from their delicate and complicated structure, the perpetuity of their movements, and the dependence of respiration on the maintenance of their physical health. Various forms of dyspnœa, emphysema, and dilated bronchi, may be the consequence of only moderate diminution of pulmonary elasticity, and a variety of symptoms, which after death are explained by no appreciable organic alterations, and which, for the sake of saying something, are referred to an unknown nervous idiosyncrasy, might simply depend on some diminution or increase of a physical property, the natural or morbid condition of which we are unaccustomed to investigate, or have no accurate means of determining. The researches of Dr. Stokes, in the paper already referred to relative to muscular paralysis from contiguity to inflamed serous membranes, may be cited as illustrations of the utility to be derived from the inquiries in question.

We will, in a future Number, venture a few reflections on the elasticity of the lung as a cause of puerile respirations, and inquire how far pressure upon the inspired air may be necessary to the healthy performance of the pulmonary functions.

Bath, 14th May, 1836.

TREATMENT OF FRACTURES OF THE STERNAL END OF THE CLAVICLE.

To the Editor of the Medical Gazette.

Sir,

Your number of the 14th instant contains a notice of a new mode of treating luxations of the sternal end of the clavicle, by M. Velpeau.

This mode of treatment I have been for some time in the habit of employing in cases of *fractured* clavicle, as I recollect, on the suggestion of M. Desault. In some instances I have made use of a triangular pouch, made of the material of bed-ticking, and padded with

cotton wool for the elbow; in others, I have relied entirely on firm bandages, applied nearly, as far as I can judge, in the manner described in that paper. By this method I conceive that the three following objects are attained:—

1st, The arm being drawn forwards over the chest, and the hand placed on the opposite shoulder, a great portion of those muscles which have a tendency to approximate the extremities of the fractured bone, and which the ordinary mode of management is adapted to *antagonize*, is completely *relaxed*.

2dly, The elbow being rather forcibly borne upwards, and pressure made beneath it in the direction of the shoulder-joint, on the injured side, a most effectual extension is obtained in the longitudinal axis of the clavicle.

This extension is rendered very evident on observing the position of the shoulder after the apparatus has been fixed, for it is elevated considerably above the level of the opposite shoulder, and directly borne away from the point of attachment between the sternum and clavicle.

3dly, By this method of treatment, those dreadfully painful bruises and excoriations are avoided which the greatest care cannot prevent, and which generally occur to a very distressing degree under the application of the figure-of-8 bandage, or shoulder-strap.

I have not had an opportunity of employing this mode in dislocation of the sternal end of the clavicle; but in all cases where extension of that bone is required, I should have perfect reliance on its efficiency in accomplishing that object with the greatest certainty, and with the least possible inconvenience to the patient.—I am, sir,

Your obedient servant,

Alfred J. Wood.

Gloucester, May 19, 1836.

ON SOME OF THE USES OF SENSATION.

Being the Substance of a Lecture delivered at the Royal Institution,

By Herbert Mayo, F.R.S.

Professor of Anatomy in King's College, London, Senior Surgeon to the Middlesex Hospital, &c.

Our sensations are of two kinds, internal and external; the former comprehend hunger and thirst, fatigue, pain, and all the other feelings which give us information of the wants or condition of the inward frame: through the latter we perceive the world around us, and learn our relation to it.

Our external sensations are referable to eight classes; of which six have special organs.

Sense.	Organ.
1. Smelling,	the nose.
2. Taste,	the tongue and soft palate.
3. Sight,	the eye.
4. Hearing,	the ear.
5. Touch or contact,	the integuments, tongue, &c.
6. Sense of effort or resistance,	the voluntary muscles.

The sensations which are not excited in special organs, but are felt through the frame generally, or in more organs than one, are,

7. Sensations of heat and cold.

8. Sensations of motion. There is a feeling attending the sudden beginning or retardation or acceleration of motion, which is independent of the sense of contact excited on one or other of the aspects of the body, and of muscular effort. When one is in a state of equable motion, as when one lies upon the ground, (there being then the earth's motion only to be taken into account), or in the perfectly smooth and uniform motion of a boat gliding down a river, we *feel* that we are at rest. Any sudden alteration of the quantity of motion in us we *feel* by the sense of motion. The existence of the same sense may be rendered evident in another manner. After travelling a short distance in a rough carriage, (to the city, for instance, in an omnibus), when the carriage has stopped, and you have remained on your seat a few seconds, if you rise suddenly, you feel, for an instant or two, as if the carriage were still in motion: this is the sense of motion continuing, *after the external cause has ceased*,—as the sensation produced by a flash of lightning remains in the eye longer than the light itself.

There are certain leading ideas respecting the external world, which are introduced into our minds collaterally by sensation. These are *locality*, *outness*, and *direction*.

Locality, or an idea more or less definite of place, attends the exercise of every sense. No one can doubt that he

smells with his nose, or tastes in his mouth; or, to put the idea in a still less disputable form, that tasting and smelling take place in the head, and not in the trunk or limbs.

Outness; the idea of something without us, as the cause of sensation, is not excited by smelling and tasting, nor by hearing necessarily, nor by changes of temperature, nor necessarily by motion; but it is irresistibly conveyed to our minds, by sensations of contact, resistance, and vision. The last instance alone is at all questionable; but it will be remembered, that when Chesselden's patient was restored to sight, he did not think himself dreaming, or lost in an inward world of sensation, but he *drew back*, thinking that the objects which he saw *touched his eyes.*

Direction.—Ideas of direction are excited in us by hearing, resistance, motion, and vision. *Simple contact* excites no idea of direction; but *series of contacts,* whether successive or simultaneous, are put together by the mind so as to convey ideas of definite extension.

Of the Sense of Direction.

1. Through hearing we obtain ideas of direction. Mr. Wheatstone has ingeniously conjectured, that our notions of audible direction may depend upon the excitation of the parts of the auditory nerve which are distributed in the semicircular canals; all, however, that we as yet *know* upon the subject (it hardly deserves to be considered a law of audition) is, that *sensations of sound are referred to a direction exactly opposite to the direction of the wave or impulse which excites them.*

2. The idea of direction obtained by the sense of effort is very definite. We believe *the direction of the resistance to be oppposite to the sensible direction of the effort.*

3. The idea of direction obtained by change of motion obeys a parallel law to what holds in the three preceding instances. The new motion is perceived to be in *a direction opposite* to the surface of contact, when the body is stopped or impelled by contact, or to the direction of the inclination of the body, when the body falls backward or to one side, or forward, in suddenly accelerated or retarded motion.

4. The law of visual direction corresponds, in a great degree, with the preceding, but not absolutely. The apparent direction of any point of an object does not depend upon the angle at which the rays proceeding from it fall upon the retina. But whatever be the angle of the incident ray, the point of the retina, on which it falls, sees *in the vertical direction only.* Nature inverted the picture of objects on the retina, in order to bring each point of the picture formed on the retina vertical to the point of the external object, the rays proceeding from which are there collected; and so to make the visual and tangible directions of objects correspond. The law of visual direction admits of easy demonstration by Mr. Mayo's experiment, of compressing the globe of the eye at different points, when the spectrum produced is found to be always opposite to the point of the retina excited to vision by the pressure made, *at whatever angle that pressure is made.*

Relation of Sensation to Instinct.

Instinct is a blind tendency to will one or a succession of voluntary motions. Particular instincts are excited by definite sensations. A feeling of uneasiness in the chest leads the new-born infant to breathe; the flavour and taste of the pleasant food introduced into its mouth leads it to swallow; a disagreeable taste leads it to sputter out that which offends it. Smell and taste are the guides of the humblest instincts. It is wonderful, however, how far they reach. Bees entertain personal aversion to certain individuals through this cause. Mr Mayo was told of a family, one individual of which, a child, is an instantaneous favourite with all dogs and tame birds which approach him. On his leaving home one day, he was persuaded to leave a cricket ball he had held in his hand during the morning; a Newfoundland dog, which belongs to the family, took the ball in his mouth, and would not part with it for some hours, even for its food. It is a wonderful fact, that in human beings this sense may become a guide to permanent personal liking and aversion, when other avenues of observation are excluded. In the case of James Mitchell, who was born blind and deaf, this phenomenon was noticed. Dugald Stewart says, " when a stranger approached Mitchell, he eagerly began to touch some part of his body, commonly taking

hold of his arm, which he held near his nose, and, after two or three strong inspirations through his nostrils, appeared decided in his opinion. If it happened to be unfavourable, he suddenly went to a distance with the appearance of disgust; if favourable, he showed a disposition to become more intimate, and expressed by his countenance more or less satisfaction."

More discrimination has been attributed to this sense, however, than properly belongs to it. It was thought by many naturalists that birds discern their prey at a distance by the scent. The following statement by Audubon shews that sight is the sense they really use.

"My first experiment," says Audubon, "was as follows:—I procured a skin of our common deer, entire to the hoofs, and stuffed it carefully with dried grass until filled rather above the natural size—suffered the whole to become perfectly dry, and as hard as leather—took it to the middle of a large open field—laid it down on its back with the legs up and apart, as if the animal was dead and putrid. I then retired about a hundred yards, and in the lapse of some minutes, a vulture, coursing round the field tolerably high, espied the skin, sailed directly towards it, and alighted within a few yards of it. I ran immediately, covered by a large tree, until within about forty yards, and from that place could spy the bird with ease. He approached the skin, looked at it with apparent suspicion, jumped on it, raised his tail, and voided freely (as you well know all birds of prey in a wild state generally do before feeding),—then approaching the eyes, that were here solid globes of hard, dried, and painted clay, attacked first one and then the other, with, however, no farther advantage than that of disarranging them. This part was abandoned; the bird walked to the other extremity of the pretended animal, and there, with much exertion, tore the stitches apart, until much fodder and hay was pulled out; but no flesh could the bird find or smell; he was intent on discovering some where none existed, and, after reiterated efforts, all useless, he took flight and coursed about the field, when, suddenly wheeling round and alighting, I saw him kill a small garter-snake, and swallow it in an instant. The vulture rose again, sailed about, and passed several times quite low over the stuffed deer-skin, as if loth to abandon so good-looking a prey. Judge of my feelings when I plainly saw that the vulture, which could not discover, through its *extraordinary* sense of smell, that any flesh, either fresh or putrid, existed about that skin, could at a glance see a snake, scarcely as thick as a man's finger, alive, and destitute of odour, hundreds of yards distant. I concluded that, at all events, his ocular powers were much better than his sense of smell.

"*Second experiment.*—I had a large dead hog hauled some distance from the house, and put into a ravine, about twenty feet deeper than the surface of the earth around it, narrow and winding much, filled with briars and high cane. In this I made the negroes conceal the hog, by binding cane over it, until I thought it would puzzle either buzzards, carrion-crows, or any other birds, to see it, and left it for two days. This was early in the month of July, when, in this latitude, a dead body becomes putrid and extremely fœtid in a short time. I saw from time to time many vultures, in search of food, sail over the field and ravine in all directions, but none discovered the carcass, although during this time several dogs had visited it, and fed plentifully on it. I tried to go near it, but the smell was so insufferable when within thirty yards, that I abandoned it, and the remnants were entirely destroyed at last through natural decay. I then took a young pig, put a knife through its neck, and made it bleed on the earth and grass about the same place, and, having covered it closely with leaves, also watched the result. The vultures saw the fresh blood, alighted about it, followed it down into the ravine, discovered by the blood the pig, and devoured it, when yet quite fresh, within my sight*."

Mr. Mayo mentioned as an instance of the accurate visual perception of birds, that a partridge was on the ground close before him, and he was some seconds before he could see it, when told where to look for it: at last he discovered it; when, the instant the bird caught his eye, it sprung upon the wing. How is it that animals know that we are looking at them, or that men judge of the direction of the sight of others?

Dr. Wollaston, in a paper published

* The details of these observations were not read in the lecture.

in the Philosophical Transactions for 1824, advanced the opinion, that we judge of the *precise* direction in which others are looking, by the direction of the other features, not of the eyes: drawing this inference from the fact that a portrait may be made to seem to look different ways—the eyes, eyelids, and eyebrows, being drawn as turned directly towards the spectator,—by changing in the drawing the disposition of the other features.

Mr. Mayo shewed that the conclusion drawn by Dr. Wollaston was not just, and demonstrated the following to be the elements upon which our conception of the direction of the vision of others is founded.

1. We judge by immediate observation of the direction of the visual axis of one eye in a living person, or in a portrait. This is the more easily determined in the case of the human eye, through the circularity of the pupil, the *concentric* circularity of the iris, and the extent of the white area in which the coloured circles are set. This distinctness of direction, so characteristic of the eye of man, may be one of the causes why the human eye has such power over animals.

2. We judge of the direction of the other eye by the same process by which we judge of the direction of the first, in looking either at a drawing, or at a living person. If the second corresponds with the first, it of course strengthens the first impression.

3. Whichever way the features are turned, if their direction is not incongruous with that of the eyes, (and, except in squinting or convulsions, in a living head it cannot be so) the correspondent action and expression of the face corroborate the impression derived from the direction of the visual axis.

4. If, as in Dr. Wollaston's figures, the other features are actually incongruous with the direction of the eyes, if the *eyes*, and *eyebrows*, and *eyelids*, are drawn with one inclination, and the forehead and nose with another, then we are puzzled; and the same eyes which would look one way in a drawing—all parts of which should be correctly designed — seem to look a different way in the incorrect drawing. So the eyes belong, in such a case, to a face looking one way, and the face belongs to eyes that would be looking another way; and our conclusions are puzzled—something as when we cross the fingers, and feel a single object double.

5. Finally, if we make a drawing of a head without eyes, and then put in one eye accordant with the rest of the features and turned towards the spectator, the unfinished portrait looks justly at us. If the other eye is then drawn, but as if turned away, or squinting, the picture ceases to appear to look at us. If, however, we cover the squinting eye, the picture again seems to look at us. Of course there is the same difficulty in telling which way a living person who squints is looking, unless he covers the eye that is directed obliquely. We can tell (as in Dr. Wollaston's figures) which way one incongruous part is looking, and which way the other, when we observe them singly. When we look at both at once, we are puzzled, by striving to reconcile things that are irreconcilable, trying to make out to what common point features are turned, that are really turned different ways; and in this perplexity we lose for the time the true direction of both.

Some of the most remarkable circumstances among the instincts or faculties of animals have to do with the sense of direction. How is it that the annual migrations of birds are decided? What is it that influences different species to travel, at particular seasons, to remote countries? No doubt some sensation renders them at those times restless, and disposed to journey, and some other sensation decides the path which they choose: but how difficult it is to imagine the nature of the blind impulse to fly a definite journey, north or south.

There is another remarkable aptitude which is shared in different degrees by all animals—a facility, namely, of finding their way home, when taken away long distances, and by means which, one would think, must have prevented all knowledge of whither or in what direction they were carried The following, from Kirby and Spence's Entomology, is one of the most striking instances on record :—

In March, 1816, an ass, the property of Captain Dundas, then at Malta, was shipped on board the Ister frigate, Capt. Forrest, bound from Gibraltar for that island. The vessel having struck on some sands at Point de Gat, at some distance from the shore, the ass was thrown overboard, to give it a chance of

swimming to land: a poor one, for the sea was running so high that a boat which left the ship was lost. A few days afterwards, when the gates of Gibraltar were opened in the morning, the ass presented itself for admittance, and proceeded to the stable of Mr. Weeks, a merchant, which he had formerly occupied, to the no small surprise of this gentleman, who imagined that, from some accident, the animal had never been shipped on board the Ister. On the return of this vessel to repair, the mystery was explained; and it turned out that Valianté (for so the ass was called) had not only swam safely to shore, but, without guide, compass, or travelling map, had found its way from the Point de Gat to Gibraltar, a distance of more than 200 miles, through a mountainous and intricate country, intersected by streams; and that in so short a period that he could not have made one false turn."

How are we to account for such instances?

It is evident that such cases are removed from the conceivable operation of direct instincts. An animal might have an instinct to fly north, south, east, or west, as it has a tendency to swallow agreeable food; but it cannot intelligibly have an instinct to guide its return to any place whatsoever, in whatever manner it may have been carried from that place; and which often would have to guide it by a different path to that by which it was brought away. It is equally certain that in such a case the animal must be guided by the recollection of the direction in which it was originally carried. The difficulty is, to conceive how it can form a recollection sufficiently accurate for the purpose, and what the sense of direction is which it uses. Let us suppose an animal (a cat, for instance) confined in a bag, and carried five miles from home, or a much greater distance, and under circumstances which would prevent its scenting its way back: if it returns (and there are many instances like this authenticated), how did it know its path, how recollect the direction in which it had been carried from home? In such cases there are probably two means employed. One is the sense of direction, dependent on motion: the creature may have observed, in its progress, each change of direction, so as to recollect at the end the mean direction in which it had travelled. This is, no doubt, more than human beings can do: but an animal, on the other hand, cannot carry away in its recollection the overture of a new opera, heard for the first time, and play it without missing a bar; but a practised performer, with a fine ear, can do this: why may not animals recollect other impressions with similar wonderful precision, although we cannot? In the cases which are now referred to, there often may occur another aid: after travelling to the neighbourhood of home, the animal may come upon some familiar track; which, possibly, may be some miles out of the true direction (its recollection of direction having served it only moderately), and by that it may be guided home: as a public speaker, who has prepared himself imperfectly for an harangue, after going something from the argument and losing himself, may come upon some old and familiar train of thought connected with the subject, and bring himself home by an often travelled path of reasoning.

In the kind of case referred to, the recollection of direction obtained by the sense of motion is probably the means which the animal employs. Or the agency of every other sense seems excluded in such instances. Where sight can be used as well, we must suppose it an important auxiliary. And the proof which we have of the extent to which animals can be aided by this sense to remember their way home, strongly corroborates the conclusion, that it is by recollected direction (obtained through different senses in different instances) that *all* the singular examples on record of this faculty in animals are to be explained.

The following facts respecting the training and powers of carrier-pigeons were obtained by Mr. Mayo from a practical person. They prove, that the carrier pigeon *sees* its way home; retracing its path in part by recollection of its several stages,—in part by recollection of visual direction.

Carrier-pigeons, of which the Dutch is the best breed, are thus trained:—At eight to ten weeks of age they begin to *run*, or to make flights of from four to five hours from the nest. They are then strong enough on the wing to commence their education. The pigeon to be trained is first taken no greater distance than a mile from home,

and tossed into the air; when, after flying round and round, and rising some height into the air, it wings its way back. This lesson is repeated five or six times in as many days. The bird is then carried to the distance of two miles and tossed. This lesson is repeated twice. The bird is next carried three miles, and tossed; and this lesson is likewise repeated two or three times. The bird is then carried six miles, and then twelve, then twenty-four, then forty-eight, then ninety-six, and so on, in a geometrical ratio. Each of these lessons is given once only. The longest flight that a carrier-pigeon has been known to make is 800 miles. In so long a flight the bird is supposed to pitch at night and roost, renewing its flight the following day.

When a trained-carrier pigeon is tossed, after making one or more circles it rises in a rapid spiral to an enormous height, before it takes its departure, and at that height it is supposed to make its journey. The speed of the Antwerp birds, which are lighter and more finely made than the English breed, is supposed to be a mile a minute. They are more extensively used than is supposed in financial transactions: one eminent speculator at Antwerp keeps 1200 pigeons. The value of a pair of well-trained Dutch birds is five pounds.

The feats of these birds, when they are used for moderate distances, are seemingly effected directly through vision: the birds *see* their way. They rise sufficiently high to command a view of distant known objects, which their fine sight enables them to recognize at immense distances. If their sight is baffled, they lose their way; so, if they set off in foggy weather, they are sometimes two, three, or four days, or even a week, in making a passage which would otherwise occupy a few hours only: sometimes, under these circumstances, they never reach home.

It is evident that at greater distances (on the rule of training described already) there must be something more than direct vision to guide them; they must rely upon recollected direction as well as upon the sight of recollected objects; or they must employ some general ideas of direction, in which, perhaps, the position of the sun may help them, in addition to the sight of known terrestrial objects.

The Use of Sensation in Voluntary Muscular Action.

Dr. Yelloly observed, that in cases of loss of sensation affecting the hand and fore-arm, the muscular action of the limb is uncertain; or an anaesthetic patient will let drop objects which he attempts to carry, whenever his attention is accidentally turned to something else. As long as the patient looks at what he carries, and so long only, he holds it safely. Mr. Mayo, in the inquiries by which he discovered the uses of the facial nerves, was led to generalize the physiological principle, that *muscular action is dependent upon sensation.* We always, and necessarily, use one or other sense to guide and measure the muscular effort made. The patient who does not *feel* by the muscular sense the weight he carries, can yet carry it steadily as long as he measures that weight and the exertion he is required to make, by another sense. In muscular action it is the senses of effort and of contact, but mostly the former, by which we are principally guided. For instance, in the performance of a piece of music on an instrument (the eye being directed to the notes), the fingers are enabled to move with precision through the muscular sense and the sense of touch. In the ordinary positions of the body, which are maintained by muscular effort, it is the sense of the effort necessary, and of the direction in which we feel it to be required, that determines and measures, *and perpetually calls our attention to*, the requisite exertion. As an instance of the substitution of one sense for another in guiding muscular motion, Mr. Mayo mentioned having observed a blind woman thread a needle: she applied the head of the needle to the tip of the tongue, and moved the end of the thread along the tip of the tongue to the eye of the needle, *seeing*, as it were, with the tip of the tongue, or by its fine sensibility guiding the muscular action of the hand which held the thread.

The Use of Sensation in maintaining Equilibrium.

In the ordinary postures of the body, which are maintained by muscular effort, we rely principally on the sense of effort; but we likewise use vision. Thus we rest or support ourselves upon visible objects, of which we know from habit the distance: *we lean*

upon our eyesight as upon crutches. This is proved, when one unaccustomed to look down heights stands on the top of a tower, resting against the parapet: he knows he is safe, but he *feels* insecure; *his eyes no longer support him;* he feels as if he would topple over.

Giddiness is another form of disturbed sense of equilibrium. If a person turn round and round, on stopping he feels vertigo; this arises, in part, from the permanence of the sensation of rotatory motion, after the motion has ceased: like the continuance of perception, *proportionately* so long after looking at an electric spark: the giddiness is kept up by the eyes continuing to move, and to pursue the rotatory sensation. A curious experiment of Mr. Wheatstone's corroborates this general law of the *temporary persistence of sensation*, pointed out by Mr. Mayo. If a person hold a large sheet of paper before his face, and fix his eyes upon a spot in the centre of it, and then turn round rapidly several times, on stopping and lowering the sheet of paper he finds himself perfectly steady in his head; he experiences in his head no vertigo, no whirling; the lines of the room are perfectly stationary, which would have been in apparent motion, had he turned round looking at them. *But his legs feel unsteady, as if actually continuing to turn round, which they are disposed to do.* The muscular sense of the rotatory motion excited is persisting, though the motion has ceased.

ABDOMINAL ABSCESS,

WITH DISCHARGE OF PUS FROM THE RECTUM AND BLADDER.

To the Editor of the Medical Gazette.

Sir,

If the inclosed case of abscess of the abdomen is worthy of a place in your journal, you will oblige me by giving it insertion at your earliest convenience.

I remain, sir,
Your obedient servant,
R. R. Robinson,
Surgeon to the London Dispensary.

King William-Street,
May 25, 1836.

Anne Wicks, æt. 7, of strumous aspect, was admitted a patient at the London Dispensary, August 13, 1835. She had two or three slight falls nine weeks ago; three weeks after which she was seized with pain in the abdomen, sickness, and diarrhœa, and became greatly emaciated. The diarrhœa continued till within a few days, since which time the bowels have been confined. On the 10th instant, a tumor was first noticed to the right of the umbilicus, which increased rapidly, and burst this morning; discharging three pints of pus. For the last twenty-four hours she has passed no urine, but has just now voided, per urethram, about ℥ij. of apparently genuine pus. She is exceedingly weak, pale, and emaciated. There is a small nipple-like elevation to the right of the umbilicus, with a central opening, from which thick genuine pus is constantly pouring. Abdomen not much distended, but very tender, especially when touched. Sickness subsided; breathing slow and natural; no motion to-day; no appetite; no sleep; tongue red, moist; clammy perspiration; pulse thready, 90.

Ol. Ricini, ℥ij. statim.
Pulv. Dov., Hyd. Cretâ, aa. gr. iij. nocte maneque.
Potass. Carbon. gr. xx.; Acid. Tart. gr. x.; Inf. Gent. Co. ℥iss. ter die.
Milk diet.

14th.—Slept well. Bowels copiously opened: two portions of the motions shewn to me; the first was of a brown colour, loose, and streaked with purulent matter; the last was lumpy and of yellow colour. But little discharge from the orifice.

Perstet.

17th.—Orifice discharges healthy pus, but not copiously; rather stronger; bowels open. Takes food, which she before refused.

Perstet.

20th.—Takes food with relish; is stronger and more lively. Vomited yesterday incessantly for eighteen hours, during which time she brought up much green bile, and some of the same purulent-looking matter that was previously seen in the motions, none of which is now visible. Bowels freely opened daily; motions yeasty, and particularly offensive. The navel somewhat swelled, and a little pus discharged from the orifice; urine quite clear; pulse slower; tongue moist.

24th.—Very much more lively and

stronger (she has twice rallied in the same way before). Orifice closed up soon after last report, and has continued closed. A slight prominence, and impulse upon coughing, in that situation. Other parts of abdomen flat, and not painful on pressure. On the morning of the **21st** the vomiting again supervened, and lasted for fourteen hours. The fluid rejected was of greenish colour, large in quantity, and deposited a gelatinous substance upon standing. Appetite good; tongue quite clean and moist; pulse fuller; no sweats; rests well; motions pale yellow.

Perstet.

27th. — Vomited slightly yesterday, and the day before, but rejected only the food taken. Has frequently cried out the last two days from pain in the back, which is rather curved. Orifice continues closed, but there is a puffiness about it. Motions much more natural in appearance, brown, figured.

31st.—Paler, and rather more feeble; sleeps well; appetite bulimious; orifice continues closed; abdomen full, from flatus; pain at epigastrium, since she ate cheese yesterday; much purged; motions loose but not at all purulent; no vomiting; urine clear; back still painful; pain also in the posterior part of the right iliac fossa.

Ol. Ricini. Perstet.

Sept. 7th.—Rejects her food at times; looks paler; is not so lively; abdomen slightly tympanitic, although she is freely purged; back still painful.

Perstet.

21st. — Vomiting has not returned; pain in bowels and back quite gone; very lively; convalescent. There is a fulness at the lower part of the abdomen, and a flatness above the navel, a cord-like constriction being situated between them.

April, 1836. — She gradually recovered strength since last report: I have just seen her, and she is so stout and healthy that I scarcely knew her.

Remarks.—Although, to those who did not witness it, much of the interest of this case must be lost, it appears to me still to possess sufficient importance to be placed on record. It was gratifying to see how well the indications were fulfilled by the means employed. The Dover's powder allayed irritation, and at once procured rest; the mercury appeared to control the inflammatory action; the saline abated the sympathetic fever; and the gentian increased the general tone of the system. I have often combined the effervescing mixture with infusion of gentian, in fever with debility, with great advantage. This case illustrates the difficulty sometimes experienced in the diagnosis of abdominal surgery. It may be asked, was this collection of matter without or within the peritoneum? If external, did it arise from inflammation of the cellular tissue, connecting the abdominal muscles, or was it the consequence of lumbar disease? In comparing this with the case of abcess in the abdominal parietes, detailed in my Dispensary Reports, in the 14th volume of the Medical Gazette, p. 365, the two, in several respects, differ; in that, although there was a pint and a half of pus evacuated by puncture, the pain in the abdomen was very slight, and there was neither sickness, constipation, or diarrhœa. In this instance, the matter appeared to come directly from the abdomen: there was no extent of inflammation of the skin, no sinus, no collection of pus under it, or any other fistulous orifice but that from which the fluid came.

In psoas abscess, the matter sometimes burrows under the abdominal muscles, and points at a distance; it generally, however, under these circumstances, finds its way to the groin; and as there was an entire freedom from pain in the back, on limping in walking, or any signs of lumbar disease, till towards convalescence, and even then they were trivial and of short duration, I do not think the formation of matter depended upon that cause, but rather consider that it came from the interior of the peritoneum, which is confirmed by its appearance in the motions, and the matter vomited. Whether it arose from abscess of the posterior of the abdominal parietes bursting into the abdomen, as in the late Mr. Burn's case, to which I alluded on a former occasion, upon abscess of the liver, simple peritonitis, or peritonitis with mesenteric disease, I will leave others to determine, whose experience is greater than mine.

The two attacks of incessant vomiting, the one for 18, the other for 14 hours' duration, the appearance of matter once, and *only once*, in the urine evacuations, and matter vomited, are curious features in the case.

FUNCTIONS OF THE CHORDA TYMPANI

IN CONNEXION WITH THE SENSE OF TASTE.

To the Editor of the Medical Gazette.

SIR,

IN the last number of the MEDICAL GAZETTE I observe an account of some experiments performed by M. Magendie, which, in the opinion of the present writer, have a tendency to elucidate the obscurity relative to the particular nerve subservient to the function of "taste." I am induced to refer especially to these experiments, in the expectation that, by repetition and variation, they may lead to the removal of what can only be regarded as an *opprobrium physiologiæ*—our ignorance of a point so essential as the nervous connexion of one of the five senses.

On first directing my own attention to this particular subject, it occurred to me that, as we had one nerve distributed to the tongue, to which no function had been assigned, it was highly probable that observation and experiment might hereafter determine that it belonged to the *disengaged* function of taste. But as opportunities of satisfactorily pursuing such a subject do but rarely occur to individuals, and being unfurnished with experiments or cases, I have not, in my latter communications upon this matter, referred to any *hypotheses* of my own; however, by your permission, I will now again press upon the attention of physiologists the importance of investigating the office of the nerve called "chorda tympani."

The experiments of Magendie, to which I have referred, consist in his having employed galvanic currents, with a view of restoring the sense of hearing in a young Polish officer, who, from an injury, had suffered a deprivation of hearing, speech, and taste; one of the wires being applied over the *chorda tympani*. "At the very first trial," says the account in your last week's GAZETTE, "an encouraging effect was produced: the patient heard a loud buzzing noise in the head. At the third application, the *sense of taste* began to be re-established: a fact of much interest for the anatomist and physiologist, as it throws light on the origin of the chorda tympani and the functions of the fifth pair."

In my first paper upon this subject, which you did me the honour to publish in the GAZETTE of October 25, 1834, after the detail of a case in which taste remained in the absence of common feeling upon the gustatory surfaces, the following remarks occur in conclusion:—"Does not the above case decide that taste is something more than a modification of common sensation? And if so, must it not, as in the case of smell, be dependent upon a specific nervous supply? And as a variety of facts show clearly that the 'true gustatory nerve' (so called) conveys both common and specific sensibility to the tongue, must it not be a compound nerve?"

What is the function of the nerve from Meckel's ganglion called *chorda tympani*, which joins the branch that goes to the tongue from the Gasserian ganglion?—of which nerve that distinguished neurologist, Mr. Swan, observes, "it is supposed that the cord of the tympanum does not unite with the gustatory, but passes in mere contact with this; but if a preparation that has been kept in spirits be carefully examined with a magnifying glass, and at the same time an attempt be made to disunite these nerves, it will be found that the filaments of both are intermixed, and cannot be separated without violence."

And, in conclusion, what is the function of the branches from Meckel's ganglion distributed to the soft palate?

I have the honour to be, sir,
Your obedient servant,
DANIEL NOBLE.

Manchester, May 24, 1836.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Outlines of Human Pathology. By HERBERT MAYO, F.R.S., Professor of Anatomy, Physiology, and Pathological Anatomy in King's College, London. Parts I. and II.

THE greater portion of the first part of Mr. Mayo's Outlines of Pathology appeared in the pages of this journal, being taken from his lectures delivered at King's College; of that part it is therefore unnecessary for us to speak. That

which now lies before us completes the systematic outline, and comprehends the digestive organs, the absorbent system, the organs of circulation, the respiratory organs, the urino-genital system, the breast, and the uterus with its appendages.

It is scarcely to be expected that any "system" should be throughout original; the arrangement, indeed, may be so, and the same merit may belong to many of the opinions, but much of the details—the mere abstract facts, must necessarily be the result of research and compilation. Accordingly, we find constant reference to the views of the most distinguished pathologists; and the writings of the best authorities, on particular subjects, are freely quoted. Thus under the head of urine we have copious illustrations from Prout; the article on the bladder owes much of its value to the lectures of Brodie; while Hewson on the blood, and Hodgson on the arteries, afford material contributions to their several subjects. It would, however, be a great injustice to Mr. Mayo, to represent him as a mere compiler, however judicious; and accordingly we find many interesting and important pathological disquisitions of his own. Among the favourable specimens both of detail and reasoning, we may mention the chapter on the arteries, which contains a large number of instructive observations, as does that on the capillaries. As a specimen, we subjoin the account which is given of the different modes in which serous effusion may be produced.

"1. *a.* The most frequent cause of effusion of serum is retardation of the progress of the blood in the veins. The effect in this instance is perhaps entirely of a mechanical nature. The capillaries being gorged, the thinnest part of the blood transudes through their coats. When the axillary vein is compressed by enlarged and indurated lymphatic glands, serum thus escapes into the cellular membrane, or the limb becomes œdematous. When the upper vena cava is obliterated by inflammation, or obstructed by the pressure of a tumor, the face, throat, and arms, are loaded with anasarca. When the inferior cava is obstructed, the legs become anasarcous. When the cavity of the femoral vein is obliterated by inflammation, the same result takes place. When the hepatic circulation is obstructed by thickening of Glisson's capsule, abdominal dropsy, or ascites, follows. When the inferior cava is compressed near the diaphragm, by induration of the pancreas or adjacent lymphatic glands, dropsy with anasarca of the legs ensues. When there is valvular disease of the heart, allowing the stroke of the left ventricle to tell backwards and impede the propulsion of blood through the lungs, and even its passage through the right side of the heart, the lungs and the whole body are liable to become infiltrated with serum. Finally, the pressure of ovarian tumors, or of dropsy, on the iliac veins, will render the legs œdematous.

"*b.* It is probable there may be a condition of the blood—such as, for instance, extreme attenuation from repeated hæmorrhage—which may dispose it to part with serum readily, and so to give rise to œdema. A thin blood and a weak heart are capable of occasioning anasarca and dropsy.

"*c.* Chronic inflammation of the kidney, impeding the secretion of urine, may be productive of anasarca. This is one of the causes of the anasarca which follows scarlatina. Dr. Bright discovered and described the influence of this cause in determining effusion in persons who have lived intemperately; and shewed its connexion with albumen in the urine.

"*d.* General effusion of serum partakes sometimes of an inflammatory character. In young and not otherwise unhealthy persons, œdema of the legs, of the arms, and face, with ascites, will sometimes supervene after exposure to cold, being attended with slight tenderness of the swollen parts, and often with albuminous urine.

"*e.* Serous effusion is a constant attendant of ordinary inflammation, exuding equally into the interstitial cellular membrane, into the cellular tissue of organs, upon serous and mucous surfaces, and upon the skin. Its source in these instances is again probably mechanical, and attributable to the obstruction of blood in the inflamed capillaries. The softening common to all fleshy textures at the outset of acute inflammation is in part at least produced by their infiltration with serum."

On the other hand, in some of the details of what might be called *medical* pathology, Mr. Mayo appears to us to be less at home. Thus there are

some observations upon the liver, particularly with regard to jaundice, in which views are put forth as new, which we believe are pretty generally entertained by physicians.

"An ordinary attack of jaundice is characterized by yellow suffusion of the skin, impaired appetite, nausea, the urine being high-coloured, the stools white. The following is perhaps the true account of the pathology of this affection.

"The yellow colour, which pervades all the tissues and most of the secretions in jaundice, is proved to be owing to the presence of bile in them; while the white colour of the feces evidently results from the want of bile in the alimentary canal. The bile has not its proper vent, and is distributed in new places. What is the mechanism of this error loci?

"Secretion is the separation of one or more elements from the circulating blood. That separation may be owing, —either to a power in the secerning organ of extracting or drawing from the blood the secretion, *previously not existing as a separate substance in it*,—or to the secerning organ allowing the matter of the secretion, *already formed in the blood*, to strain through and find vent,—or to both these causes conjoined.

"The result obtained by M. Simon, in some experiments made upon pigeons, favours the second supposition. He found, that, when the kidneys were removed, the blood became loaded with urea. This single fact would lead us to conclude analogically, that the elements of *all the other* secretions are evolved in the blood in the course of the general circulation, and that the organs in which they are commonly thought to be formed only give them passage. The bile we may thus conclude to be formed, not in the liver, but in the mass of the circulating blood.

"Again, secerning organs are liable (to use indeed a doubtful expression) to be palsied; in other words, their secretions are liable to be *suppressed*. The best instance of this phenomenon occurs in the pathology of the kidney: suppression of urine forms a well-marked and very formidable complaint. In this instance another remarkable feature makes its appearance. The secretion being stopped, and the usual vent for the elements of the urine being obstructed, *they appear in other places*: urea has thus been found in the peritoneal serum in cases of suppression of urine.

"Reasoning from the above premises, I am disposed to believe that ordinary cases of jaundice depend upon suppression of bile—that the bile, abnormally accumulated in the blood, finds vent in the secretions of other parts, which thence become coloured yellow. Additional circumstances might be mentioned, which corroborate this view. Bile is detected in the blood of jaundiced persons; while the liver in those who have died of jaundice is generally pale, and without bile."

Now, that some of the worst forms of jaundice (those attended with disposition to coma passing into fatal apoplectic affections) are dependent upon the bile not being eliminated, or, in other words, on its being suppressed, is a doctrine which, we can vouch for it, has been taught by some of the medical lecturers of London for these ten years.

Such, in a general way, is the character of this work — such are some of the points in the manner of its execution which deserve unqualified praise—and such some of those in which it admits of improvement.

We have no doubt but that it will take its place on the same shelf with Mr. Mayo's kindred production — the Elements of Physiology; and we presume the author would find no reason to be dissatisfied with such measure of its success. To give any general *outline* of "Outlines," would be a hopeless task; but we have done enough to enable the reader to judge sufficiently whether the work is suited to his wants.

MEDICAL GAZETTE.

Saturday, May 28, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

REGISTRATION OF BIRTHS AND DEATHS.

THE question how far medical men are to consider themselves the servants of the public—doing public duties of an arduous and an onerous kind gratui-

tously—is one which it becomes every day more and more expedient to solve. We confess, that with respect to certain services (as, for example, that of attending and giving professional evidence at coroners' inquests), we never heard any thing, in the shape of a reasonable argument, against their just claim to remuneration. It is urged by some persons, who, from the fact, may be presumed to know very little about the matter, that medical men ought to perform such *slight* offices without fees and without grumbling, inasmuch as they enjoy certain immunities—such as from serving on juries, in the militia, &c.—which should be looked upon as fully an equivalent. But we can safely appeal to the better judgment of those who have thought more deeply on the subject: as we pointed last week to the reasons why we deemed medical referees entitled to fees for warranties of life-assurance, taking into account the importance of the service required to be rendered, as well as the anxious and delicate position in which it places the medical man in respect to his friend, or patient; so, with regard to inquests, we might even more strenuously insist on the right of recompense for the time occupied, and the special preparation necessary for giving good evidence—evidence so indispensable, that, without it, a conscientious coroner and his jury cannot feel themselves absolved from the obligation of their oaths.

The same is true respecting various other functions which medical practitioners are called upon to perform, in behalf of their brother members of the community, without fee or reward. The consequence is, that by a sort of prescriptive use, there is no profession more cavalierly treated. Not only has the government, or the legislature, never yet thought proper to recognize an order of medical men to be consulted on occasions demanding their special assistance for the due administration of justice, but when necessity presses, the casual attendance of very questionable persons claiming to belong to the medical profession is deemed sufficient. At the same time, in every case of trial for manslaughter by quackery, the obnoxious law is quoted, by which the regularly educated practitioner, and the presumptuous empiric, are placed exactly on the same footing. Yet medical men seldom protest against these anomalies, but tamely proceed in whatever path of apparent usefulness is opened before them.

We are sometimes tempted to be indignant, when, with such instances of neglect or ill-treatment fresh in our recollection, it is sought to impose new duties, of a public kind, on members of the profession. But a consideration of the possible utility of such duties generally interferes, and we think no more of by-gone annoyances. So we fancy it is with the great mass of practitioners: they are carried onward by their zeal and their ardour for the profession, and they willingly seize any collateral opportunity of being serviceable in the business of the state.

These remarks have been suggested by the announcement of a new plan for the registration of births, marriages, and deaths, in the working of which, medical men may be of the most essential service, and in the success of which, it must be admitted that the profession will have no small interest.

Of the great utility of exact registers of births and deaths, conducted on a large scale throughout the empire, every well-informed member of the medical profession must be convinced. The statistics of population, of disease, of epidemic and contagious disorders, and the elucidation of their causes, depend mainly on our possessing such registers, filled with the requisite data, trust-

worthily gathered, and lodged with the proper authorities regularly appointed for the purpose. Such an arrangement as would effectually secure these advantages has long been a desideratum, but is, we think, likely to be supplied ere long, through the active zeal and intelligence engaged on the project both in and out of parliament.

About two years ago, Mr. W. Brougham, brother of the late Lord Chancellor, prepared a registration bill which received general approbation, and nearly passed the House of Commons; but that measure has since been abandoned as wholly impracticable. Lord John Russell's bill has been substituted in its stead,—in many respects perhaps superior to its predecessor, but still greatly clogged, and promising to be very cumbrous in its mode of operation. Perhaps, too, in its very origin it may be deemed faulty: for it was got up with a view principally to relieve some grievances of the Dissenters, and we believe it is not intended to apply to the wants of either Ireland or Scotland; whereas such a measure should rather have been contemplated as a great, and broad, and highly interesting question of legislation, fraught with importance to every individual in the British empire.

A third plan has been suggested, by a gentleman, not in parliament, who appears to be well acquainted with all the intricacies of the subject, and has favoured the public with his views. In certain "Observations on Lord J. Russell's Bill," the author, Mr. James Yates, has given a very interesting account of what we conceive to be a very superior arrangement, in many respects, both as regards its simplicity and feasibility. We shall take leave to enter a little into detail with reference to Mr. Yates's plan.

As to its immediate machinery, it is to be observed, that in all the discussions on this point, it has been agreed, that instead of raising a wholly independent establishment for registration, it were better to attach the system to some existing institution. Mr. W. Brougham proposed to combine it with the business of collecting the assessed taxes, and Lord J. Russell with that of administering the poor laws. Mr. Yates, however, thinks that the Post-Office affords the best facilities, not only as an institution universally known, but the one through which, at all events, the work of registration must chiefly be conducted.

Certain forms or schedules are proposed by Mr. Yates, as those which he thinks most available for the purposes of registration; three of them, corresponding to each act of birth, marriage, or death, are required—one to be held by the party chiefly concerned, or his nearest relation, the second by the local post-office, and the third to be deposited in the metropolitan establishment. We have no objection whatever to these schedules—which, indeed, we consider as eminently simple, and suited for the purpose intended; but, perhaps, an extract from what Mr. Yates says respecting the quantity of them necessary for registration, will give a good idea of the amount of business in the registering department likely to be done throughout the country when the measure comes into action:—"To form an idea," he says, "of the quantity of these forms that would be used, I may mention that, on the supposition of a birth for every 36 persons in a population of 24,300,000, the number of copies of the form in Schedule A [for the births] required for one year would be 675,000. In like manner, allowing a death for every 50 persons, and a marriage for every 128, the number of Schedule B [for the deaths] required for one year would be 486,000, and the number of

Schedule C [for the marriages] 189,000. Thus the total amount of certificates of the three classes would be 1,350,000. From these numbers, which must be regarded only as approximations, it results, the average length of each form being taken at two feet, that the paper required for the process would extend to 500 miles in length!"

The principal source of revenue for liquidating the expenses of this prodigious registration is to be found in the fee of a shilling, payable on occasion of entering each birth and death, and something more for each marriage. Fines also are to be levied in case of procrastination; for instance, if a birth be not registered within a fortnight, a shilling additional is to be paid for every week elapsed subsequent to that appointed period.

A point of great importance, in respect of medical statistics, is secured in Mr. Yates's form of registering the deaths. The *cause* of death, it is intended, shall be regularly entered in the schedule, and there is space left for *remarks*, to be filled up by the proper witness,—namely, whenever it is at all practicable, by the medical attendant. This is a provision which is completely overlooked in Lord J. Russell's bill.

The whole system proposed by the author whose plan is before us, goes upon this principle—that man is not a mere passive material, but "a moral agent, having from his birth certain rights, certain claims to protection, certain relations to those around him, which may become the sources of many advantages. The French law, being of modern growth, and having been formed with an enlightened regard to general principles of jurisprudence, distinctly admits the latter view. It supposes every man to have an *état civil;* that as soon as he comes into the world he is to be considered not merely as one of the ingredients, of which the vast mass of the population is composed, but as a distinct person, occupying his own place in society, and entitled, according as his place may be, to consideration, protection, employment, and advancement."

Mr. Yates, however, judiciously combines both views: "on the one hand, to provide for the security of every individual in the possession and advancement of his rights, and to require the aid and co-operation of himself and his nearest connexions in making this provision; and, on the other hand, to obtain for the whole mass of society advantages, in which they have a common concern, and to impose upon the whole mass such united efforts as are necessary to obtain them."

Of the curious shifts to which persons are frequently put in order to make out their title to certain disputed rights, we meet with instances almost daily. The following is given by the author, as an example of the difficulties which often arise in attempting to prove pedigrees in the present state of the law. In the case of *Slaney* v. *Wade*, which occurred but a short time since in the Court of Chancery, it was necessary to go back more than two hundred years, and to prove births and deaths through several branches of a numerous progeny from that time to the present. With reference to one branch, the plaintiff was fortunate enough to obtain the evidence of an old man, who formerly held some parochial office at Shiffnall, in Shropshire, and who had once copied, in pencil, an inscription on a mural tablet in the church. This inscription had afterwards been traced over in ink by the clergyman, and preserved with one or two other documents of the same kind. In making some repairs, the tablet was plastered over; and consequently the copy (probably made in a

very careless manner) was taken as the best evidence that could be procured.

It is needless, we imagine, to pursue this subject further. The advantages of being possessed of a good system of registration must be obvious to every thinking man in the community; to none more so than to the members of our profession, who are well aware of the benefits which would be thence derived to medical science. How far it may be practicable to substitute Mr. Yates's plan for the more cumbrous and expensive one of Lord John Russell, we know not; but this we know, that if simplicity of design, economy of resources, and the absence of all violent change in the existing order of things, can recommend one project in preference to another, that of which we have given the reader some account in the present brief notice must supersede all that have hitherto been proposed to the public. We have been the more desirous of giving publicity to the principal details of the plan, inasmuch as we are convinced that its adoption will materially conduce to the advancement of science, and that, with such an object in view, none can be more interested in its success, as none have more power to patronize it in society, than the members of the medical profession.

INSULT TO THE MEDICAL OFFICERS OF THE GRENADIER GUARDS.

The indignity offered some time back to the Surgeons of the Navy, in prohibiting them from going to Court, must be fresh in the recollection of our readers. We have now to record another of those petty insults which are occasionally offered to our profession, by those who seem to hold that the rank of different members of society is to be estimated inversely as their intelligence and usefulness.

Some balls have recently been given at St. James's, on which occasions the attendance of the officers of the Guards was commanded by her Majesty. It was arranged that half of the officers of each regiment should attend in succession; and, accordingly, those of the Coldstream, of the Life Guards (and, we believe, of the 3d Regiment), including the medical officers, had the honour of being present. But with regard to the Grenadier Guards the arrangement was different, the commanding officer having directed the attendance of the other officers, *to the exclusion of the surgeons;* thereby clearly intimating that, in his estimation, the medical men were not in a situation to entitle them to the same honour.

We recommend to the parties who were made the subjects of this invidious distinction to appeal to his Grace the Duke of Wellington, as Colonel of the regiment, who, we feel satisfied, would not lend his sanction to such a proceeding; or, failing this, humbly to apply to his Majesty, to know the meaning of the term "gentleman," by which each of them is designated in his commission, and which bears the Royal signature.

IRISH MEDICAL ESTABLISHMENTS.

In that part of Dr. Borrett's report on the Medical Institutions of Ireland, given in the present number, some statements will be found which, we venture to say, will astonish the reader not a little. We call attention particularly to the very extraordinary system of misrule which appears to have been pursued for several years past, at the North Charitable Infirmary, Cork. The mockery of a board of trustees, or of managers, at that place, is at once one of the most ludicrous and offensive displays of the mode in which *charity* is dispensed in

some parts of Ireland, that, we think, we have ever heard of; though we fear that several examples of a similar kind might, without difficulty, be pointed out in the same ill-regulated part of the empire. The account given of the Cork Lunatic Asylum cannot fail to be read with interest: nor shall we forbear, in this passing notice of his paper, to say how heartily we concur with Dr. Borrett in his remarks on the unwise and unjust system of exclusion, maintained in the appointments to the County Infirmaries, in favour of the *Irish* Colleges of Physicians and Surgeons. There is not a more barefaced monopoly existing: yet the Colleges in question have been labouring to *protect their rights* in the apprehended *reform* of the medical corporations!

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, May 24, 1836.

H. Earle, Esq., F.R.S., President, in the Chair.

Sir Benjamin Brodie's elaborate paper on *Injuries of the Spinal Marrow*, was brought to a conclusion this evening. We hope to give an account of it next week. The reading of the paper was followed by a discussion, in which Sir Benjamin, Mr. Earle, and several of the Fellows, took a part.

The next meeting of the Society (June 7)—an extraordinary one, for despatch of business—will be occupied with abstracts of several papers, which cannot be read in full in consequence of the time of the Society being limited, the season now coming to a close; and on the same evening several eminent persons, including Tiedemann, Tommasini, and others belonging to various Universities throughout Europe, will be balloted for, as honorary Fellows. The business of the Society on that evening will commence at eight o'clock.

ROYAL INSTITUTION.

Friday, May 13, 1836.

Dr. Lardner on the Economical Production of Steam.

The nominal subject on which Dr. Lardner gave the lecture of this evening, was the practicability of steam communication with India; but at least three-fourths of what he delivered related to the economy of water and fuel in preparing steam. Of the perfect practicability of reaching India expeditiously, by the route of the isthmus of Suez, and having one or two supplies of fuel at certain localities on the way, nobody can entertain a reasonable doubt: Dr. Lardner also pointed out a course by which a more expeditious communication between this country and the United States of America might be effected, laying down railways in Ireland in the first instance, putting to sea in the Bay of Galway, and touching at Newfoundland as an intermediate and convenient point in the voyage to New York. Of the various facts stated by the lecturer in the earlier portion of his discourse, we may notice one which will give a good idea of the manner in which the production of steam is limited in attempting to accomplish long voyages. The quantity of fuel consumed by the boiler of a steam vessel is calculated at 10lbs. per hour for each horse power: therefore a ton of coals is burned every hour, when there are two engines at work, each 100 horse power. It follows that, supposing the speed of the vessel to be seven miles an hour, 300 tons of coals, at the very least, would be required for the completion of a voyage of 2000 miles: and probably it would not be safe to venture on such a voyage without having on board 400 tons, in order to meet contingencies and accidents. How much such a stowage of coal must interfere with the speed and usefulness of a vessel intended for despatch, is obvious. It is rather a curious fact that the boilers of engines on land are found to consume one half more fuel than marine boilers: in other words, that 15lbs. per hour for each horse power is their calculated consumption. The probable reason of this Dr. Lardner did not explain; he gave it merely as a fact admitted by the best informed practical men.

Friday, May 20, 1836.

Professor Mayo on Sensation, and some peculiarities of Vision.

The large and mixed auditory which heard this lecture seemed much interested by the facts and illustrations brought be-

fore them; but as a complete abstract of the lecture itself will be found in another part of the present number, we shall not here, even if we had the requisite space, offer any analysis of it.

GREATEST ASCENTS IN THE ATMOSPHERE.

M. Boussingault, in company with Colonel Hall, on the 15th of December, 1831, ascended Chimborazo, to the height of 6,606 metres (19,699 feet), the greatest elevation which has yet been attained on land, Humboldt having been able to reach as high only as 19,400 feet. M. Gay Lussac, in a balloon, rose to 22,900 feet at Paris. The barometer carried by Boussingault fell to 13 inches 8 lines. The temperature in the shade was 7·8 C. (45.60 F.) This chemist thinks it possible to live in rarefied air. Thus, at a height almost equal to that of Mont Blanc, where Saussure had scarce strength to consult his instruments, young women may be seen in South America dancing during the whole night. The celebrated battle of Pinchinca during the war of independence, was fought at a height little inferior to that of Mount Rose. The guides who accompanied Saussure, assured him that they had seen the stars in broad day. Boussingault never witnessed them, although he reach d a much greater altitude.—*Journ. de Chim. Médic.*

PRIZES OFFERED IN PARIS.

The Editors of the *Annales d'Hygiène et de Médecine légale* propose to give two prizes, of 300 fr. each, one for the best essay on some subject relating to public *hygiène*, the other for a similar production on a subject of legal medicine. The papers may be written in Latin, French, German, English, Italian, or Spanish; and must be forwarded before the 1st of Nov. 1836, to M. J. B. Baillière, the publisher, of Paris. The name of the author to be inclosed in a separate sealed billet.

NEW MEDICAL WORKS.

Treatise on the Preservation of the Teeth and Gums. By W. Thornton, M.R.C.S., Dental Surgeon. 8vo. pp. 51.

Observations on the Medical and Surgical Agency of the Air-pump. Read before the British Association in 1835. By Sir James Murray, M.D. &c. 8vo. pp. 63.

Archiv für Anatomie, Physiologie, und Wissenschaftliche Medicin. Herausgegeben von Dr. Johan. Müller. Jahrgang, 1836, Heft 1. Berlin.

LITERARY ANNOUNCEMENT.

The Proofs of Infanticide considered: comprising a Summary of the present state of medico-legal knowledge on the subject of Child Murder. By Wm. Cummin, M.D., Lecturer at the Aldersgate School of Medicine..—(Nearly ready.)

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

May 26, 1836.

William Henry Wood, Ash Hall, Glamorganshire.
Charles James Cox, London.
John Henry Roberts.
Walter Moore.
Samuel Potter, Liverpool.
Richard Wise Norris, Liverpool.
Robert Wallis, South Shields, Durham.
George Arnott, Edinburgh.
John Selkirk, Bury, Lancashire.

LECTURES ON MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

By Jon. Pereira, Esq., F.L.S.

Lecture XXXVI.

I propose in this lecture to examine *Iron*, and its *pharmacological compounds.*

IRON.

History and synonymes.—This metal (called by the alchymists *Mars*) was known in the most ancient times, probably more than 3000 years before Christ. It was employed medicinally at a very early period,—namely, above 3200 years ago. Indeed, it appears to have been the first mineral used internally; and a curious anecdote is given of its introduction into medicine. Melampus (a shepherd supposed to possess supernatural powers) being applied to by Iphicles, son of Phylacus, for a remedy against impotence, slaughtered two bulls, the intestines of which he cut to pieces, in order to attract birds to an augury. Among the animals which came to the feast was a vulture, from whom Melampus pretended to learn that his patient, when a boy, had stuck a knife wet with the blood of some rams into a consecrated chestnut tree, and that the bark had subsequently enveloped it. The vulture also indicated the remedy—namely, to procure the knife, scrape off the rust, and drink it in wine for the space of ten days, by which time Iphicles would be lusty, and capable of getting children. The advice thus given by Melampus is said to have been followed by the young prince with the most perfect success!

Native state.—This metal is found in both kingdoms of nature. Thus the magnet will detect it in the ashes of most vegetable substances; for example, the roots of *helleborus niger*, *daucus carota*, and *polygala senega;* the flowers of the *papaver rhœas;* and the seeds of *sinapis.* In the blood and some other parts of animals it is also found. In the inorganic kingdom it is met with in the *metallic* state, in the form of *oxide*, *sulphuret*, *chloride*, and *oxy-salts.*

Extraction.—In this country *clay iron ore* (essentially a *proto-carbonate* of iron) is roasted, to expel carbonic acid, water, sulphur, and other volatile matters; and then smelted with a flux and coke, by which cast iron *(ferrum fusum)* is obtained. This, however, contains carbon, oxygen, silica (or silicon), and often sulphur and phosphorus. To separate these it undergoes the processes of refining, puddling, and welding, to form wrought iron *(ferrum cusum)*, which is the purest kind of commercial iron.

Properties.—Most of the physical properties of iron are too well known to require description. The primitive form of the crystals of meteoric iron is the regular octahedron: the tenacity and ductility of this metal are great, but the malleability is not at all proportionate. When pure, its colour is said by Berzelius to be white, like silver. One property deserves notice, namely, that by rolling or drawing into wires, the specific gravity of iron diminishes. Its atomic weight is 28, and its symbol Fe.

Characteristics.—Iron readily dissolves in dilute sulphuric acid, with the evolution of hydrogen gas. The solution contains the protosulphate of iron, and produces on the addition of caustic potash or soda, a greenish white precipitate, (the hydrated protoxide); this precipitate, by exposure to the air, attracts oxygen, and is converted into the red or peroxide. By boiling the solution with a little nitric acid, we obtain a persulphate of iron, recognized

by ferrocyanuret of potassium causing a blue precipitate; sulphocyanic or meconic acid, a red colour; gallic acid, or infusion of galls, a bluish black; and succinate, or benzoate of ammonia, a yellowish precipitate.

Physiological effects. — Iron is probably inert as long as it retains its metallic form, but it readily oxidizes in the alimentary canal, and thereby acquires medicinal power. As acids promote this chemical change, acid wines and fruits assist in rendering the metal active, while alkalies and their carbonates have an opposite effect. The oxidizement of the iron is attended with the evolution of hydrogen gas, which gives rise to unpleasant eructations. If sulphur be taken along with the iron, sulphuretted hydrogen is developed. Like the ferruginous preparations generally, the internal employment of iron causes blackening of the stools. The nature of the effects produced by the oxide of iron formed in the alimentary canal, will be best examined hereafter under the head of ferruginous preparations. I may, however, remark here, that it is one of the few metals which, by oxidizement, is not rendered more or less poisonous.

Uses.—Iron filings have been used in those cases where the chalybeate preparations generally have been administered, and which I shall presently notice. In some instances, however, the efficacy of the iron depends on its being in the uncombined state. Thus, when used as an antidote to poisoning by the salts of copper, it is necessary that the iron be in the metallic state, in order to reduce the cupreous salts. Iron filings have been regarded as anthelmintic, especially in the small thread-worm (the *oxyuris vermicularis*); they have been used also as an astringent application, to repress fœtid secretion of the feet.

Administration.—Except in poisoning by the cupreous preparations, modern practitioners very properly prefer the compounds of iron to this substance in the metallic state, considering them to be more certain and active. Sydenham, however, seems to have had a different opinion, for in speaking of the treatment of hysterical and hypochondriacal diseases, he says, "I have been fully satisfied by frequent experience, that the bare substance performs the cure sooner and more effectually than any of the common preparations of it; for busy chemists make this, as well as other excellent remedies, worse rather than better, by their perverse and over-officious diligence."

Iron filings (designated in our Pharmacopœias by the terms *ferri ramenta*, *ferri limatura*, and *ferri scobs*) are usually obtained from smiths and other workers in iron. They are separated from the filings of copper and brass by a magnet; and are given in doses of from five grains to half a drachm, in the form of powder, electuary, or pill. As a *powder*, they should be mixed with some aromatic, to enable them to be retained better on the stomach. To form them into an *electuary*, we may employ honey; and when we wish to administer them in the form of *pill*, they may be combined with some bitter extract, or with the fœtid gums. As they are usually met with in commerce more or less oxidated, part of the medicinal effect is attributable to the oxide present.

Ferruginous or Chalybeate Preparations.

Physiological effects.—To save much repetition, I purpose speaking of the ferruginous compounds collectively, since they operate in an analogous manner. The *local* effects of the sulphate and chloride of iron, are those of irritants, and these preparations accordingly rank among poisons; but they are not equal in power to the mercurial and cupreous salts. Most of the ferruginous preparations are astringent; that is, they constringe the parts with which they are in contact, and thereby diminish secretions and check sanguineous discharges. Thus, when swallowed, they repress the secretion and exhalation of the alimentary membrane, and thereby render the alvine evacuations more solid, and even occasion costiveness. The sulphate and chloride of iron are the most powerful of the ferruginous astringents. Administered in large quantities, or when the alimentary canal is in an irritable condition, all the compounds of iron are capable of exciting heat, weight and uneasiness at the præcordia, nausea and even vomiting, and sometimes purging.

The constitutional or *remote* effects of the chalybeates are principally observed in the vascular and muscular systems, and are best seen in that state of the system denominated *anæmia*, or more properly *hypæmia*, in which both the quantity and quality of the blood appear defective. You have a good illustration of this state in chlorotic patients. The skin appears pale and almost exsanguineous, the cellular tissue is œdematous, and, after death, the larger vessels as well as the capillaries are found to be imperfectly supplied with blood. Patients with this condition of system suffer from great feebleness, loss of appetite, and palpitation of the heart; and in females the catamenial secretion is frequently, but not invariably, defective. That the want of uterine action is not the cause, but rather the effect of this condition of system, seems tolerably clear from the circumstance of the same constitutional symptoms of anæmia some-

times occurring with a perfect regularity of the uterine functions; moreover, we occasionally meet with anæmia in men. It is sometimes the consequence of hæmorrhages—at other times it occurs spontaneously, and without any known cause.

If in this condition of system iron be administered, the appetite increases, digestion is promoted, the pulse becomes fuller and stronger, the skin assumes its natural tint, the lips and cheeks become more florid, the temperature of the body is increased, the œdema disappears, and the muscular strength is greatly augmented. The alvine evacuations assume a black colour, as they always do under the use of the ferruginous preparations, owing to the formation of what might perhaps be termed *ferrate of iron*—that is, a mixture, or perhaps rather a compound of the per- and protoxide of iron,—and which, by some chemists, is regarded as a third oxide of iron, under the name of the black or deutoxide. After continuing the use of the iron for a few weeks, we frequently find excitement of the vascular system (particularly of the brain); thus we have throbbing of the cerebral vessels, and sometimes pain in the head; and by the long-continued use of these preparations an inflammatory condition of the system follows, with a tendency to hæmorrhage. Mr. Carmichael considers the *sanguine* temperament (marked by a high complexion, celerity of thought, remarkable irritability of fibre, and a quick pulse) as depending on an excess of iron in the system; whereas he regards the reverse of this (namely, the *leucophlegmatic*, or what I have termed, in a previous part of the course, the *relaxed*, temperament, and which is characterized by a pale bloated countenance, dull eyes, mind heavy and slow in receiving and forming ideas, little irritability of fibre, and pulse small and feeble) as depending on a deficiency of iron.

Whether these notions are or are not correct, is of little consequence to my present object. I wish to point out the two conditions of the system,—in the one of which iron is prejudicial, in the other serviceable,—and I leave others to form hypotheses on these facts.

When by the use of iron the state of the general system improves, the secretions assume their natural condition, and thus at one time we observe this metal promoting the uterine discharge; at another, checking it, according as chlorosis or menorrhagia had been previously present; we cannot, therefore, regard the preparations of this metal as having any direct emmenagogue effect, as some have supposed.

It is said that in animals to whom iron has been given for a considerable time, the spleen has been found smaller, harder, and denser, an effect which is supposed to be owing to the increased contractile power experienced by the veins of the abdomen. The liver even is said to be influenced in a somewhat similar, but slighter manner.

In the condition of system (*anæmia*) we have been examining, I have mentioned that the blood is observed to be deficient in quantity, and to be altered in its quality. Now some refer all the other symptoms to this abnormal state of the circulating fluid, and ascribe the beneficial influence of iron to its improving the quality of this liquid. It is certain that frequently under the use of the preparations of this metal the blood acquires a more scarlet colour, owing, as it has been fancied, to an increase in the quantity of its colouring particles; and it is said that the crassamentum becomes firmer and more solid, and even increased in quantity. This alteration of the physical and chemical properties of the blood is supposed to render it more stimulating, and thus the different organs receiving a fluid of a more healthy character, resume their normal condition, and perform their functions in a proper manner. In favour of this mode of explaining the therapeutic influence of iron, I may remark that it appears indisputably established, that, taken as a medicine, this metal does become absorbed, for Tiedemann and Gmelin have detected it in the serum of the blood of the portal and mesenteric veins of horses and dogs, to whom they administered either the sulphate or chloride; occasionally, too, the urine has been found to contain it. Moreover, Menghini asserts the quantity of iron in the blood of dogs is increased by feeding them on substances mixed with this metal. Furthermore, it is not to be forgotten, that iron exists in no inconsiderable quantity in healthy blood, and is supposed to contribute to its colour, and probably to its stimulant properties; so that it is not unlikely any variation in the quantity of this metal would be attended with an alteration in the action of all the organs.

Now, herein consists one remarkable distinction between iron and most other metals: to act beneficially on the system, it would seem to require digestion and assimilation, whereas the others become neither digested nor assimilated; they get into the blood, it is true, but they then act as poisons, and gradually disorder the functions, and undermine the general health. However, it appears that iron is a substance not easily digested, for it remains in the stomach and intestines many days after it is swallowed; in order,

therefore, that the ferruginous preparations should have much effect on the general system, it is necessary that they be employed for some considerable time. Another circumstance connected with the operation of iron is likewise deserving of notice,—namely, that it has no primary or specific effect on the nervous system, as arsenic, mercury, copper, zinc, bismuth, silver, and many other metals have. You must not, however, imagine from these remarks, that the preparations of iron never operate injuriously. On the contrary, we see them sometimes acting as local irritants on the alimentary canal, as already noticed: and by the use of them in too large quantities, or for too long a period of time, they bring on a hypersthenic or phlogistic diathesis.

Uses.—By a careful attention to the known physiological effects of iron, the indications and contra-indications for its employment may be in great part learned. Thus you will readily see the impropriety of administering it where there is irritation or inflammation of the alimentary canal, in plethoric habits, and in persons disposed to inflammatory diseases, or to apoplexy. On the contrary, in all cases characterized by feebleness and inertia of the different organs of the body, by a soft lax condition of the solids, and by a leucophlegmatic state of the system—where the patient appears to be suffering from a state of general anæmia, already described—the preparations of iron are admissible. It is hardly within the scope of my present object to instance particular diseases where this metal may be used, but rather to point out those conditions of system which affect the employment of iron in diseases generally. I may notice a few cases by way of illustration.

As an *external* or *local* agent, we rarely employ the preparations of iron, since we have other more efficacious and powerful remedies. Occasionally, however, they have been used as astringents, styptics, and caustics. Thus solutions of the sulphate and chloride have been used in the form of injection, in discharges from the urethra and vagina: and the tincture of the muriate is now and then applied as a styptic, or to repress the growth of spongy granulations.

The ferruginous preparations are principally resorted to, with the view of affecting the general system. Thus *affections of the sexual organs* are frequently treated with advantage by iron. It is hardly necessary to stop here to inquire whether iron has any specific influence over these parts, since those who deny this influence (and you will see, from the tenor of my remarks, that I am among this number) equally admit the beneficial operation of this agent in various disordered conditions of these organs. Thus chlorosis, amenorrhœa, dysmenorrhœa, and menorrhagia, are at times benefited by chalybeates; but, on the other hand, they are occasionally unaffected by them, and in some cases even may be made worse. For example, when chlorosis depends on, or at least is accompanied by, that condition of the system before described under the name of anæmia, you will very frequently find ferruginous preparations useful; but if it occur in patients of a full habit, or if it arise from inflammation of some organ (as the lungs, stomach, or bowels), chalybeates will do harm. I have already given you an anecdote illustrative of the early use made of iron as a remedy for impotence; and I may add, that in those cases connected with, or arising from, general feebleness, it may be now and then useful; but in nine out of ten cases which we are called on to treat, this condition arises from indulgence in bad habits, which no medicine can affect. Sometimes iron is resorted to in sterility (though Dioscorides says the rust of iron hinders women from conceiving), but the conditions under which it is likely to be useful are precisely those before mentioned for other diseases. In discharges from the genital organs, as gleet and leucorrhœa, the internal employment of the tincture of the muriate of iron, sometimes conjoined with the tincture of cantharides, has been found useful.

In some *periodical diseases*—namely, ague, asthma, and tic douloureux—the ferruginous preparations have gained considerable repute. In the first of these diseases, (that is, ague), the sulphate has been used by Marc and others, the subcarbonate by Buchwald, the ammoniacal muriate by Hartmann; but it has been almost wholly superseded, of late years, by the sulphate of quinine and by arsenic. In asthma, Dr. Bree (who was himself a sufferer from the disease) regards iron as preferable to all other remedies. However, the experience of others has not confirmed his favourable opinion of it. The preparation called subcarbonate of iron has latterly been extensively employed in tic douloureux, and with variable success; in some cases acting in a most extraordinarily beneficial manner, in others being of no avail.

In *diseases of the spleen and liver*, the ferruginous compounds are occasionally found useful. I have already alluded to the influence which they are supposed to possess over these organs; a supposition the more probable from the occasional remarkable effects produced by them in diseases of these organs. "I regard iron as

a *specific*," says Cruveilhier, "in *hypertrophy of the spleen*, or *chronic splenitis*; whether primitive, or consecutive to intermittent fevers." After noticing the symptoms attending this condition (such as paleness of the lips, &c. great lassitude, abdominal and cephalic pulsations, brought on by the slightest exertion; pain at the left side, disordered state of the digestive organs, accelerated pulse, and heart easily excited), he goes on to remark, "By the aid of iron I have obtained the complete resolution of enlargements of the spleen, which have occupied half, or even two thirds, of the abdomen." In hypertrophy of the liver, iron has not been equally serviceable.

Some years ago the preparations of iron were strongly recommended in *cancer* by Mr. Carmichael. The grounds on which he was led to the use of them were, the probability that cancer had an independent life,—in other words, that it was a kind of parasite, as some preceding writers, more particularly Dr. Adams, had presumed; and secondly, the efficacy of iron in destroying intestinal worms, which led him to hope that it would be equally destructive to other parasites. With these views he employed (externally and internally) various ferruginous compounds—namely, the ferretartrate of potash, the subcarbonate of iron, and the phosphates. Whatever hopes may have at one time been entertained of these remedies as curative agents, in this most intractable disease, they are now completely destroyed. That these medicines are occasionally useful as palliatives, may perhaps be admitted; but they have no curative powers. Indeed this might have been suspected, from the hypothetical grounds on which they were introduced into use. The proofs of the parasitical nature of cancer must be much stronger than any yet offered, ere we can admit this hypothesis. Moreover, the preparations of iron, though useful, are not so "very effectual" in worms as Mr. Carmichael's remarks would lead you to imagine.

In certain affections of the digestive organs, the preparations of iron are occasionally used with benefit,—as in some forms of dyspepsia, but only in the conditions of system already noticed. In some *affections of the nervous system*, which occur in weak debilitated subjects, it is also used; for example, in epilepsy, chorea, hysteria, and the shaking palsy produced by the vapour of mercury.

I might enumerate a considerable number of diseases, besides those already mentioned, in which chalybeates are occasionally beneficial; but the general principles regulating their use will be readily comprehended from the remarks which have been made; and I have only to add, that in all diseases attended by debility, and marked by atony and inertia of organs, more especially in those indicating a disordered state of the hæmatose functions, the preparations of iron will be in most instances more or less serviceable. Furthermore, I may enumerate scrofula, rickets, dropsy, and gout, as diseases in which iron has been at times used with advantage.

Peroxide of Iron.—Subcarbonate of Iron of the Shops.

History and synonymes.—The powder sold in the shops by the name of *subcarbonate of iron* (sometimes termed *precipitated subcarbonate*, or merely *carbonate*) is, really, *hydrated peroxide of iron*, with a small portion of *protocarbonate*. Now, Geber was acquainted with peroxide, and probably it was known before his time, though of this we have no proof.

Native state.—Protocarbonate of iron is met with native, both massive and crystallized, and is termed *spathose iron*, *clay iron ore*, &c. The mineral called *brown spar* consists of the protocarbonate and peroxide of iron. Many mineral waters contain protocarbonate of iron, but when they come in contact with the air, carbonic acid is evolved, while the protoxide attracts oxygen, and is deposited under the form of red peroxide.

Preparation.—It is prepared by mixing solutions of the protosulphate of iron, and carbonate of soda (called in the Pharmacopœia subcarbonate). Double decomposition takes place, a greenish hydrated protocarbonate of iron precipitates, while sulphate of soda remains in solution.

Re-agents.	Results.
$\dot{Fe}\ \dddot{S}$	$\dot{Na}\ \dddot{S}$
$\dot{Na}\ \ddot{C}$	$\dot{Fe}\ \ddot{C}$

In the act of drying, the green protocarbonate attracts oxygen from the air, gives out carbonic acid, and becomes the red peroxide of iron. Even when prepared with the utmost care, the greater part of the protocarbonate undergoes this change.

Composition.—Protocarbonate of iron is composed of—

1 atom protoxide of iron	36
1 atom carbonic acid	22
	58

Its formula being $\dot{Fe}\,\ddot{C}$

And peroxide of iron consists of—

1 atom iron	28
$1\frac{1}{2}$ atoms oxygen	12
	40

Its formula is $\underline{\dddot{Fe}}$

Now the subcarbonate of iron of the

Pharmacopœia is a mixture of these compounds; the proportions, according to Mr. Phillips, being as follows:—

	As met with in the shops.	Prepared with the greatest care.
Protocarbonate iron........	4	40
Peroxide iron	96	60
	100	100

Properties. — The subcarbonate of the shops is a red, tasteless, odourless powder, insoluble in water, but dissolving in the mineral acids with the evolution of carbonic acid (from the contained protocarbonate).

The *physiological effects and uses* of the subcarbonate of iron are similar to those of the ferruginous preparations in general; and, therefore, do not need further notice, except perhaps in reference to *neuralgia*, or *tic douloureux*, in which this compound was first recommended by Mr. Benjamin Hutchinson; and of its occasional beneficial effects there can be no question. We cannot explain its *modus operandi*, and, therefore, for the present, must content ourselves with the valuable fact of its occasional remedial powers. I say *occasional*, because you will meet with many cases in which no benefit whatever is gained by its use; nay, in one case where I employed it, the patient fancied it made her worse. No one, however, would omit trying it in this disease. Mr. Carmichael, as already mentioned, has recommended it as a remedy for cancerous diseases; but the fact of its having fallen into almost general disuse in this complaint, is a sufficient evidence of its inefficacy. As an antidote for arsenic, it has, I think, little claim to notice. Its agency can be mechanical only, as I have observed in speaking of the antidotes for arsenic.

Administration.—The usual dose of this preparation, as a tonic and emmenagogue, is from ten grains to half a drachm, given with some aromatic, to enable it to sit more easily on the stomach. In tic douloureux, however, much larger doses are given,—from half a drachm to two or three drachms.

Protocarbonate of Iron—Compound Iron Mixture.

History.—This is a professed imitation of Dr. Griffiths' antihectic or tonic mixture. Hence it is frequently termed "*Griffiths' mixture.*"

Preparation.—It is prepared by adding protosulphate of iron to a solution of the carbonate of potash (called, in the shops, the subcarbonate) in rose-water; to which powdered myrrh, spirit of nutmeg, and sugar, have been added. Immediately the mixture is made, it is to be put into a stoppered bottle, to prevent it undergoing decomposition.

The *theory* of the process is similar to that mentioned for the last preparation. By the mutual action of the ferruginous sulphate and the alkaline carbonate, we obtain sulphate of potash in solution, and protocarbonate of iron precipitated. To prevent this latter salt attracting oxygen from the air, it is to be placed in a stoppered bottle; otherwise it would become converted into the peroxide. As more subcarbonate of potash is ordered in the Pharmacopœia than undergoes the above change, the excess acts on the myrrh and forms a saponaceous compound, which assists in suspending the protocarbonate in the liquid.

Properties.—When first made, this mixture has a greenish colour, owing to the protocarbonate of iron; but by exposure to the air it becomes reddish, in consequence of the formation of peroxide of iron and the escape of carbonic acid: hence we should only prepare this mixture when wanted for use.

Physiological effects.—It is, according to the experience of myself and others, one of the most efficacious forms for administering iron, and which is supposed to be owing to its being the most soluble, and, therefore, the most digestible, ferruginous preparation. The myrrh contributes to its tonic operation.

Uses.—It is admissible in any of the cases in which the ferruginous preparations generally are employed.

Administration.—It is given in doses of from one to two ounces, repeated three or four times a-day.

Protocarbonate of Iron—Pilulæ Ferri Compositæ.

The compound contained in the London Pharmacopœia, under the above title, is analogous, in its composition and effects, to the compound iron mixture just described. Thus it is composed of myrrh, subcarbonate of soda (not potash, on account of its deliquescence), sulphate of iron, and sugar: by the mutual action which the second and third of these ingredients exert on each other, we get sulphate of soda and protocarbonate of iron formed. These pills, like the mixture, should only be made when wanted. Twenty grains contain about one grain of protoxide, or one grain and seven-tenths of the protocarbonate of iron, and are equal to an ounce and a half of the mixture; and, therefore, the dose of the pills will be from ten to twenty grains.

Protosulphate of Iron.

History and synonymes. — This salt is mentioned by Pliny under the names of *misy, sory,* and *calchantum.* It has been known by various other appellations, such as *sal martis, green vitriol, copperas, vitriolated iron,* &c.

Native state.—There are two sulphates of the peroxide found native, as also a double salt of the protosulphate of iron and sulphate of alumina. These are described in Dr. T. Thomson's work on Mineralogy.

Preparation. — Protosulphate of iron is prepared by dissolving clean unoxidized iron in dilute sulphuric acid. The solution is to be filtered, evaporated, and crystallized.

In this process a portion of water is decomposed, the hydrogen of which escapes, while the oxygen unites with the iron to form protoxide of iron, which with sulphuric acid, yields the protosulphate.

Re-agents.	Results.
Fe	H
$\dot{H}$	$\dot{Fe}\,\dddot{S}$
$\dddot{S}$	

The *green vitriol,* or *copperas* of commerce, is usually obtained by exposing heaps of moistened iron pyrites (bi-sulphuret of iron) during some months to the air. The pyrites gradually attracts oxygen, and is converted into sulphate of iron, which dissolves in the water. The solution thus procured is usually acid, and hence old iron is added to saturate it. It is then concentrated in leaden boilers, and run off into large vessels to crystallize.

Properties.—The primary form of the crystals of this salt is the oblique rhombic prism: their colour is blueish-green, but by exposure to the air they attract oxygen, and become yellowish. Its taste is styptic, or inky.

Characteristics.—That it contains sulphuric acid is readily proved by the barytic salts, as mentioned when speaking of this acid. If it be a pure protosulphate, it yields a white precipitate on the addition of the ferrocyanuret of potassium, but which becomes blue by exposure to the air. Usually we obtain a blueish precipitate on the addition of the ferrocyanuret, owing to the presence of some peroxide of iron; the lighter the blue colour, the purer the salt. The common *green vitriol,* or *copperas,* yields a much deeper blue precipitate than the Pharmacopœial preparations, in consequence of a larger portion of the per-sulphate present.

Composition.—Crystallized pure protosulphate of iron consists of—

1 atom protoxide iron	..	36
1 atom sulphuric acid	..	40
7 atoms water	....(9×7)	63
		139

Its formula, therefore, is $\dot{Fe}\,\dddot{S}\,7\dot{H}$.

In almost all cases a little persulphate is mixed with the protosulphate.

Physiological effects.—This is, in its local action, one of the most powerful of the ferruginous salts. In *large doses* it acts as an irritant, and when swallowed, produces pain, vomiting, and purging. This has been shewn by the experiments of Dr. Smith on dogs, as well as by a case recorded in one of the German magazines, of a girl who took about an ounce of the salt, and suffered for seven hours with colicky pains, vomiting, and purging. Taken in *smaller doses* it acts locally as an astringent, diminishing the quantity of intestinal fluids, while its constitutional or remote effects are similar to those of the ferruginous preparations generally.

Uses.—Sometimes it is employed as a local agent; for example, as a styptic applied to bleeding from a number of small vessels, or as an astringent applied to ulcers or mucous membranes, to diminish secretion, as in ophthalmia, leucorrhœa, gleet, &c. Internally, it is objectionable where we require the long-continued use of iron, on account of its powerful local effects, whereby it is apt to disorder the digestive organs.

Administration.—The dose is from one to five grains.

Tincture of the Chloride of Iron.

This compound is called in the Dublin Pharmacopœia, the *liquor of muriate of iron.* Its usual denomination is *tincture of the muriate of iron.*

Preparation.—It is prepared by dissolving the powder called, in the Pharmacopœia, subcarbonate of iron, in muriatic acid, and adding rectified spirit of wine to the clear liquid.

Theory. — The subcarbonate of iron of the shops is, as I have before mentioned, a mixture of peroxide and protocarbonate of iron. By digestion in muriatic acid some water is generated, the per-and proto-chlorides of iron are formed, while carbonic acid gas escapes. The two chlorides dissolve in the spirit. By the action of the free muriatic acid, or the chloride of iron, on the alcohol, a little muriatic æther is formed, which is readily detected by the smell.

Properties.—It is a reddish or yellowish-brown solution, having a sour styptic taste, and an odour resembling that of muriatic æther. By exposure to the air the

protochlorde of iron attracts oxygen, forming peroxide of iron, which is precipitated, and the sesquichloride is left in solution: the peroxide is thrown down for want of free muriatic acid to dissolve it. When prepared according to the directions of the College, its specific gravity is 0·994; but Mr. Phillips found that the tincture of commerce varied in its specific gravity from 0·951 to 1·030. This doubtless depends on the varying strength of the muriatic acid.

Composition.—This preparation contains

Perchloride of iron.
Protochloride of iron.
Muriatic æther.
Rectified spirit.

If prepared according to the London Pharmacopœia, half a fluid ounce of the tincture should yield, by the addition of an alkali, $16\frac{8}{10}$ grains of peroxide of iron, which, of course, comes from the decomposition of $30\frac{24}{100}$ grains of the perchloride. Mr. Phillips has found the tincture of commerce to yield from $9\frac{3}{10}$ grains to 20 grains of peroxide.

Physiological effects.—This is, in its local action, one of the most powerful of the preparations of iron. The free muriatic acid which the tincture of the shops frequently contains, contributes to increase its irritant properties; and in Dr. Christison's work on Poisons, you will find a brief notice of a case in which an ounce and a half of this tincture was swallowed, and death occurred in about six weeks,—the symptoms during life, and the appearances after death, being those indicative of inflammation. The general or constitutional effects of this preparation do not appear to differ from those of the ferruginous compounds generally.

Uses.—It is sometimes, though not frequently, used as a local agent. Thus it is applied as a *caustic* to venereal warts, and to spongy granulations. As an *astringent* it is sometimes employed as a local application to ulcers attended with a copious discharge; or as a *styptic*, to stop hæmorrhage from numerous small vessels.

Internally, it is frequently used in gleets and leucorrhœa, often in combination with the tincture of cantharides; also in spasmodic stricture. In passive hæmorrhages from internal organs (as the kidneys, uterus, and bladder), it is likewise administered. In scrofula it has been used as a tonic. Its other uses are similar to the ferruginous compounds generally,—always recollecting its powerful local action, and, therefore, that in cases requiring the long-continued use of iron, it is less advisable than some other ferruginous preparations whose local effects are milder.

Dose.—The dose is from ten to thirty minims, taken in some diluent.

Ferrum Ammoniatum.

History and etymology.—This compound, which was known to Basil Valentine, has had various appellations, such as *flores salis ammoniaci martiales*, *ferrum ammoniacale*, or *ferrum ammoniatum.*

Preparation.—In the Pharmacopœia it is ordered to be prepared by dissolving the powder, called subcarbonate of iron, in muriatic acid, filtering the solution, and evaporating. The residuum, mixed with muriate of ammonia, is to be sublimed. The usual method, however, of forming it, is by mixing a solution of chloride of iron with a solution of muriate of ammonia, and evaporating to dryness.

Theory.—When the subcarbonate of iron of the Pharmacopœia is mixed with muriatic acid, two chlorides of iron are formed (the per- and the protochloride), a little water is generated, and carbonic acid escapes. By the evaporation of the solution with a solution of muriate of ammonia, the chlorides of iron, and the muriate of ammonia, mix and combine to form this compound.

Composition.—According to Berzelius, it is to be regarded rather as the result of the simultaneous crystallization of muriate of ammonia and perchloride of iron, than as a true chemical combination of these two salts. Mr. Phillips states that the quantity of peroxide of iron obtained from 200 grains of this salt, was in one case $2\frac{1}{10}$ grains, in another 3 grains.

Properties.—It is met with in the shops in yellow or orange crystalline grains, having a feeble odour, and a styptic saline taste.

Effects.—It produces the general effects of the ferruginous preparations; but, on account of the small and variable quantity of iron present, it is a compound which is of little value. The muriate of ammonia present renders it slightly aperient.

Uses.—It has been employed in glandular swellings, in amenorrhœa, and other cases where the preparations of iron are usually employed.

Administration.—It may be given in substance in doses of from four to twelve grains. In the London Pharmacopœia there is a *tincture* made with proof spirit. According to Mr. Phillips, 13 fluid drachms of it are equal to 1 fluid drachm of the tincture of the muriate of iron.

Ferrotartrate of Potash.

History and synonymes.—This preparation was first described by Angelus Sala, at the commencement of the seventeenth century. In the Pharmacopœia it is

termed *tartarized iron*. It has been known by other appellations, such as *chalybeated tartar*, and *tartarized tincture of Mars*.

Preparation.—It is prepared by rubbing iron and bitartrate of potash together, then adding water, and exposing the mixture to the air for about twenty days. It is afterwards boiled in water, the solution filtered and evaporated, and the residuum rubbed to powder.

Theory.—The iron decomposes a portion of the water, disengaging its hydrogen, but attracting its oxygen to form protoxide of iron, with which a portion of the tartaric acid of the bitartrate combines to form prototartrate of iron. By exposure to the air this salt attracts more oxygen, and becomes pertartrate of iron, which unites with the tartrate of potash to form a double salt, namely, the ferrotartrate of potash.

Composition.—Mr. Phillips says it consists very nearly of—

Peroxide of iron........	20
Bitartrate of potash	80
	100

The peroxide of iron is presumed to be in combination with part of the tartaric acid of the bitartrate, forming thus a tartrate of iron, which performs the function or part of an acid, or electro-negative, to the tartrate of potash, constituting thus a double salt,—the *ferrotartrate of potash*. That the oxide of iron is a constituent of the acid portion of the salt, seems shewn by the fact, that neither the alkalies nor their carbonates precipitate it; nor does ferrocyanuret of potassium produce a blue precipitate with it, unless an acid be added.

Properties.—As met with in the shops it is an olive-brown inodorous powder, having a styptic inky taste, and reacting as an alkali. It dissolves in about four times its weight of water, and is slightly soluble in alcohol. It is deliquescent, probably from the tartrate of potash it contains.

Physiological effects.—In most of its effects this preparation agrees with the ferruginous preparations generally. The peculiarities of its operation seem to be these: it is less constipating, and is thought to be less exciting to the vascular system than some other chalybeates.

Uses.—We rarely use this compound, but it may be administered in most cases in which iron is indicated.

Administration.—The dose of this compound is from ten grains to half a drachm, in the form of solution or bolus—combined with some aromatic, to prevent its disordering the stomach.

Solution of Ferrotartrate of Potash—Vinum Ferri.

History.—I have already related to you the story told by Apollodorus, of the recommendation of iron wine by Melampus for impotence, more than 3200 years since.

Preparation. — This compound is prepared by rubbing iron-filings with the supertartrate of potash, and exposing them with water to the air for several weeks, by which a ferrotartrate of potash is formed, as in the last preparation. This is dissolved in sherry or Rhenish wine, or, according to the last edition of the London Pharmacopœia, in a mixture of spirit and water.

Composition.—It is a solution of the ferrotartrate of potash, with excess of the bitartrate of potash. Made according to the directions of the London College, Mr. Phillips states, a pint of the wine contains 16 grains of the peroxide of iron; so that *a drachm* of the tincture of muriate of iron would contain as much iron as *four ounces* of this wine. It is very absurdly termed *vinum* ferri, since it contains no wine.

Physiological effects.—The effects of vinum ferri are those of the ferrotartrate of potash combined with those produced by spirit.

Uses.—It is employed in chlorosis and other cases calling for iron. The objection to it is the small quantity of iron it contains.

Dose.—It is given in doses of from one to three or four drachms.

Liquor Ferri Alkalini.

This preparation was formerly termed *tinctura martis alcalisata stahlii.*

Preparation.— Dissolve iron in dilute nitric acid, then add it to a solution of subcarbonate of potash, frequently shake the mixture, and afterwards pour off the solution.

Theory.—By the action of iron on nitric acid we obtain pernitrate of iron, and binoxide of nitrogen.

Re-agents.	Results.
$4\ \overset{\therefore\cdot\cdot}{N}$	$\overset{\cdot\cdot}{N}$
$2\ Fe$	$\overset{\cdot\cdot\cdot}{Fe}\ 3\ \overset{\therefore\cdot\cdot}{N}$

This solution of pernitrate of iron, with excess of nitric acid, is then mixed with the solution of subcarbonate of potash: nitrate of potash is formed — carbonic acid escapes, and peroxide of iron precipitates; this, however, is speedily re-dissolved by the combined agency of the carbonic acid, and the excess of subcarbonate of potash employed. By standing, part of the nitrate of potash crystallizes.

Composition.—It is not quite certain in what mode of combination the ingredients of this mixture exist. In all probability

it is to be regarded as consisting essentially of the *ferro-carbonate of potash;* that is, as a double salt, composed of the per-carbonate of iron as the acid, and carbonate of potash as the base. Each fluid drachm, according to Mr. Phillips, contains nearly two grains of peroxide of iron.

Properties.—It is a dark brown-red liquid, transparent, and of an alkaline taste.

Physiological effects. — It possesses the general properties of the chalybeates, and in addition, those of an antacid.

Uses.—I believe it is never used in this country.

Dose.—The dose is from 30 minims to a drachm, or even more than this.

Iodide of Iron.

History and synonymes.—This compound, sometimes termed *ioduret*, or *hydriodate of iron*, was introduced into use as a medicine by Dr. A. T. Thomson.

Preparation.—It is readily procured by adding 30 grains of iron filings (or iron wire in small pieces) to about 100 grains of iodide, contained in about 14 fluid drachms of distilled water. Heat the liquid, to drive off the excess of iodine, until it become colourless, filter, and evaporate to dryness.

Properties.—Prepared as now mentioned, it is an opaque grey mass, with a metallic lustre; very deliquescent, and when dissolved in water forming a green solution, which, by exposure to the air, absorbs oxygen, deposits oxide of iron, and is converted into periodide of iron.

Composition.—It consists of—

1 atom iodine	126
1 atom iron	28
	156

Its formula, therefore, is Fe I.

Physiological effects.—Its local action is that of an irritant; its remote effects are supposed by Dr. Thomson to be those both of iron and iodine already mentioned. Whether the iodine is thrown out of the system in the form of iodide of iron, or of an alkaline iodide, has not yet been satisfactorily ascertained.

Uses.—It is indicated where we wish to have the combined operation of iodine and iron; as in scrofula, chlorosis, amenorrhœa, glandular enlargements, some forms of bronchocele, &c.

Doses.—From two to four grains dissolved in water, flavoured with orange-peel.

REPORT

ON THE

MEDICAL INSTITUTIONS OF IRELAND.

By Wm. P. Borrett, M.D.
Assistant Commissioner for inquiring into the state of the Irish poor.

(*Communicated by the Author.*)

[Concluded from p. 324.]

SUPPLEMENTARY OBSERVATIONS AND SUGGESTIONS RESPECTING THE SANITARY STATE OF THE DISTRICTS VISITED.

Having completed my account* of the different medical institutions which came under my observation—having noticed their constitution, management, and control, their practical operation, and the abuses and defects to which they are severally liable—I might at once bring my report to a close, as having satisfied the points of inquiry to which I was especially directed. But having been at some pains to make myself acquainted with the actual condition of the poorest classes by personal inspection, and having with this intention visited the sick and indigent at their own dwellings, in company with the medical and other gentlemen who attended at our examinations, I shall better, I think, attain the object proposed to me by the Board, if, before I conclude, I allude briefly to the sanitary state of the districts which I traversed, and to the amount, as well as to the nature and cause, of the diseases which were prevalent, for the proper and effectual treatment of which the medical institutions have been established. But so much has been already laid before the public in reference to these matters through the labours of commissions, through parliamentary investigations, and various official documents and returns, that it is unnecessary for me to go into lengthened details; and further, I have already adverted to them in the first part of my report, under some of the heads into which the subject of the dispensaries is divided.

It cannot be a question with those who are at all conversant with the description of hospital-patients, such as they are met with in the two countries, that there is not only a greater amount of disease, but that it is of a more aggravated and malignant character in Ireland, generally speaking, than in England, in Dublin than in London. And the cause must be as

* See last number of the Med. Gaz.

evident to an unprejudiced observer as the fact itself. It is to be attributed to the greater destitution and distress of the Irish than the English people, to their being worse lodged, clothed, and fed, and to the more general and excessive use among them of spirituous liquors. To point, as some persons are wont to do, to a few sturdy and robust individuals, whose stamina and natural powers have been proof against the debilitating circumstances of their condition, and to argue thence for the general excellence of their physical state, for the wholesomeness of their food, and in favour of their mode of life and habits, is to make the exception the rule. Those who *have mixed with the lowest* classes in Ireland, whether in town or country, know full well how much more frequent are wan and haggard countenances, shattered constitutions, and the signs of a premature old age, than the expression of blooming health; and will recollect how often they have turned in pity and disgust from the painful and sickening scenes presented to them by squalid decrepid human objects, disfigured by disease, or a complication of abject penury and disease.

In the rural districts, and in the outskirts of towns, the poor Irish, generally speaking, live in huts or cabins of mud or loose stones. Each hut consists of but a single apartment, and nothing is to be seen within but a pot to boil potatoes with, a truss or wad of dirty straw, and some rags for a coverlid, under which the different members of the family creep at night, herding together for the sake of animal warmth, and often in a state approaching to nudity. The straw is not changed for six months together, although a few pence would purchase enough for a bed. Sometimes a table and a couple of stools may be seen, and even a dresser, with some crockery-ware, but these and other common articles of furniture are for the most part wanting. The pig is invariably found in the same apartment. He has his corner assigned to him, and is considered to have the best right to be accommodated, as he furnishes the means of paying the rent. The muck heap, next to the pig, is an object of especial care. The children are employed in scraping the dung off the roads, and collecting materials of filth and ordure from all parts. Unless they can accumulate sufficient manure for the patch of potato-ground, the crop, or in other words, the very means of subsistence, would fail. A lane or alley is made up of rows of cabins of this kind, each cabin having its dung-heap treasured up under the window, if there be one, or by the door, with its constant accompaniment of a pool of stagnant water, each cabin being occupied by one or two families, with from four to six individuals in each family; so that the lanes are floating in filth, or stopped up with rubbish and dirt, and poisoned with noxious effluvia. If the poor dwell in houses instead of huts, it is surprising how many a house is made to contain. Partitions are run across each room for the accommodation of two or more families. The landlord never repairs, but leaves the houses to crumble about the tenants' heads. The rent is about one shilling per week for a whole room, or eight pence for half, so that a small house of four or six rooms will bring in a yearly rent of 12*l.* or 15*l.*

When visiting these cabins, I have found the inmates so destitute of clothes, that they were unable to leave their homes, and they had often parted with every thing, even to the rags on their backs. The catholic clergymen told me it was a common thing for them to stop away from chapel for want of clothes. I recollect on going to visit a sick patient with the medical attendant to the dispensary at Athlone, (Westmeath side), that I saw a grown-up girl skulking in the corner of the cabin, who was ashamed to be seen, and unable to go out in search of employment, because she had no decent clothes to put on. But it would be impossible to enumerate the various instances of utter destitution and distress of this kind which came before me. Those alone which I saw at Cork, in company with the Rev. Mr. Egan, would suffice to fill a volume, and the picture of extreme misery bore the same revolting character, although it might be shadowed out a little more darkly in one place than in another, whether in Bantry or Kinsale, Kenmare or Killarney, Strokestown, or elsewhere, in the three counties which I visited in the course of my inquiry.

To the want of clothing and exposure to wet and cold it was usual for medical men to refer the great prevalence of pulmonary affections. Coughs, colds, rheumatic pains, together with consumptions, in those who were predisposed by constitutional taint, or the combining influence of impoverished diet, were caught by lying on the damp straw and the earth floor, broken up and holding pools of water. Bowel and stomach complaints, and innumerable cases of a dyspeptic form, were ascribed to the potato diet, or rather to the poor partaking of the potato when unfit for use, either from decay, or from its being unripe, or imperfectly cooked. The coarsest kind of potato, called a "lumper," is preferred, from its producing a more exuberant crop, and from its much larger size. It is eaten when only parboiled, as it goes further in this state; it sits

heavier upon the stomach, and prevents the feeling of inanition for a longer time. In most places it forms the only kind of food to the poor, who eat it dry, morning, noon, and night, if they can afford three meals a day; or, at best, with the addition of a little milk, or the variety of a salt herring. Wheaten bread, an egg, or piece of bacon, are luxuries they never think of. Although it did not seem to be the general opinion of the medical men, that the constant use of any one article of food, if wholesome, would of itself be productive of disease, still they were agreed that the potato diet, for the reasons just stated, must be more or less injurious to the general health. The food, too, generally given to children was by no means adapted to their tender age. Infants of 12 months old are often fed upon fish in maritime towns, and it is a common practice with the wretched mother to sustain her offspring by transferring to it the morsel of potato which she has first prepared by masticating it herself. Such digestible substances as barley, oatmeal, and rice, are scarcely attainable, on account of their cost, trifling as it is.

The season of the year at which the poor are particularly driven to subsist upon bad food, is in the interval between the consumption of the old stock of potatoes and the coming in of the new crop; and upon referring to the Dispensary-books it will be found that there is an increase of gastric and enteritic affections, of pyrosis, diarrhœa, dysentery, &c. during these months. It is precisely at this period, too, that fever is apt to prevail. The existence of fever in a greater or less degree may be taken as a criterion of the poverty of the people, especially in regard to the supply of food.

The scarcity at this time may be so great, that the poorer classes are obliged to have recourse to weeds and shell-fish, or what else they can collect along the shore, for sustenance. A yellow weed, known by the name of "prassick," and found every where growing among the corn, was pointed out to me as affording a common means of support. During the months of last June and July, there was a great dearth of agricultural employment, and so much destitution in consequence, that many persons actually perished from want. The truth of this statement was attested in particular by the medical attendant of the Dispensary at Kildorrery, by the Roman Catholic clergyman of the same place, and the gentlemen present at the examination. It was not, they remarked, from the scarcity of potatoes, and their consequently high price, that this took place, for potatoes were selling at 6*d*. per weight of twenty-one pounds during the whole time; but solely and entirely from the utter inability on the part of the poor to buy them at all. If potatoes, they continued, had been only 2*d*. or 3*d*. per weight, they would have been alike beyond their means. It was no uncommon occurrence at the time for labourers to work merely for their daily food; and while they were receiving it at the farmers' houses, their wives and families went entirely unprovided for. Nor was this state of distress confined to the labouring classes alone; several instances occurred where gentlemen became security to millers for sacks of flour, in favour of respectable farmers, who were unable to purchase themselves. No relief was obtained from government, and the only aid which the poor received consisted of about fifteen pounds collected at the Roman Catholic Chapel, and laid out in purchasing meal, which was distributed daily to some hundred individuals. The parish priest stated that government advanced some money to one or two of the neighbouring parishes, but he was not acquainted with the circumstance at the time, otherwise he would have made application in behalf of his own flock.

Before quitting Kildorrery I went with the medical officer to see a poor woman who had been recently delivered of twins. I found her in a wretched hovel, and in a state of utter destitution, as she had been obliged to dispose of her crop of growing potatoes during the prevalence of the distress which has been detailed above. Her husband, she said, was out at work, but he received no pay for his labour, as he was only employed to work out some assistance which had been rendered to him at the time of the general pressure.

Thus subject to a periodically occurring scarcity, and wretchedly fed at other times,—exposed to the vicissitudes of the climate, to wet and cold, to the pernicious influences of bad habitation and clothing,—exhausted by task-work, or toil undergone for a stipulated wage, or desponding for want of employment,—distressed by many combining causes of a moral and physical kind constantly warring against their health, and predisposed by their debilitated state,—where is the wonder that the Irish poor are peculiarly liable to disease—that fever, dysentery, and other contingently contagious complaints, become rife at particular seasons, and spread with a frightful violence through entire districts, sweeping off the inhabitants by large numbers at a time.

In 1817, it appears from a report published upon the subject of the contagion, that one million and a half of persons, upon a moderate calculation, suffered from fever; and of this number at least 65,000 died. Although since that time there has been no epidemic attack, still cases of

fever have constantly occurred. I saw several of a bad typhoid form when I visited the fever hospitals in the latter part of the summer of 1834. Of late years the ravages of a contagious fever had been superseded by the terrible scourge of cholera, which seemed to have the power of converting other forms of disease to its own type. It was observed by medical men, that fevers and other complaints had materially declined since this epidemic appeared. It ravaged Ireland in 1832, 1833, and 1834, and attacked several places twice, and a few even three times (Bantry, Tralee, &c.)

In general, through the active interposition of the better classes in behalf of the sick poor—whether as an act of charity or of self-defence, it matters not —and through the adoption of proper precautionary means, a check was put to the progress of the pestilence, and the proportionate number of deaths did not exceed those which occurred in other countries afflicted by the same visitation, although, from the wretched condition of the people, a greater mortality was to be feared. Those who were better off exerted themselves to meet the public calamity, and administered the money which was raised by subscription and advanced by the government, in the best possible way. Streets were swept, manure and filth removed, lime thrown into the sewers, cabins white-washed and supplied with clean straw, clothes and bedding fumigated, hospital accommodation provided, and the services of medical men secured. A perfect confidence prevailed among all classes, and none of the sick refused to enter the hospitals, with the exception of a few places only, where some disturbances occurred at the first outbreaking of the disease; as at Athlone, &c.

But the above wise and humane regulations were not always carried into effect. Through their entire neglect at Strokestown, upon the second irruption of the cholera, the worst consequences ensued. At the examination into the affairs of the Dispensary, the Assistant-Commissioners were furnished with a list of those who died of the epidemic, containing upwards of sixty names; and a melancholy description of the ravages of the disease, and of the utter abandonment and distress of the people, was given by those who were eye-witnesses of the scene. The Catholic clergyman stated that he went about from house to house, accompanied by some of the persons present, to try and collect a few shillings for nurse tenders and coffins. He found the doors of the dwellings of the poor in many instances open, and the wretched inmates lying about the apartment, ill and unable to help themselves, and so crowded together that he was obliged to step over them in order to get to the side of those who stood most in need of his services. There was no one to be found to render any assistance, or even to remove the dead. Those who were well off had fled at the first report of the return of the disease, and for several weeks the place was deserted: no markets were held, no business transacted of any kind. On the first visitation of the cholera the usual means had been taken to meet the calamity, but nothing was attempted on the second attack—no board of health appointed—no medical men engaged—no money raised by subscription, and even the house was withheld which had served as an hospital the first time, although thirty pounds had been expended out of the general fund belonging to the town in raising it one storey, roofing it with slate, and putting it in complete repair. It was therefore considered a hardship, and, indeed, unjust, that the use of this house should not have been allowed to the inhabitants on the recurrence of the disease, or at least that some other house was not offered in lieu of it. It may be added, that the whole town and neighbourhood belong to a nobleman who is an absentee for ten months out of the twelve, and that no information could be obtained of the agent, in regard either to the grievance just cited, or the state of the funds of the Dispensary to which he was the treasurer; since he declined forming one of the meeting, upon the ground that "he did not see what good would result from the inquiry."

The demoralizing tendency of *dram-drinking*, and the hideous amount of poverty and disease which the habitual indulgence of this vile passion has produced among the lower classes, are too well known to need additional notice or confirmation: yet it is an evil of such a magnitude, that it cannot be passed over in any inquiry relating to the moral or physical condition of the Irish poor.

Owing to the great cheapness of whiskey, and the extraordinary facilities and encouragement which are given to its sale, its use, even to excess, has become universal, and almost attained to a maximum consumption, having reference to the amount of population. In a few places, perhaps, its use had declined; a fact to be rather ascribed to the actual inability of the people to purchase it, than to the operation of habits of sobriety and the influence of any moral principle. In general, however great their distress, they contrive to find means for the gratification of this favourite passion. Misfortune seldom fails to make the sufferer a drunkard, even if he happen not to be already addicted to spirituous drinking. The small farmer,

who, if his own statement can be believed, is unable, for want of capital, to till his land to the most advantage, never concludes a bargain except over drink, and rarely leaves the market sober. The mechanic, while he deplores that he has no means to purchase tools, gets the more intemperate the less he earns; and the labourer who goes without the common necessaries of life, and is covered with rags, consumes his fair-days, holidays, and Sundays, in drink. Perhaps fishermen are the most improvident of all classes—their occupation being a kind of lottery, and their gains most precarious, and irregularly made. They receive a portion of the sales of the fish they catch in lieu of wages. These they expend in whiskey, making no reservation against the future. At sea they drink to keep out wet and cold; on shore, they plead as an excuse for drinking, the hardships they undergo in being exposed nights and days, in open boats, at sea. Sunday being a day for recreation and rest, it is the chosen time for tippling. The laws for shutting-up public houses are not enforced, nor is it usual with magistrates to fine or punish for drunkenness. In towns where they still commit for this offence, the gaols are crowded. The mode of licensing public-houses, by which they have been prodigiously multiplied of late years, as well as the exceeding cheapness of whiskey, must contribute to its inordinate consumption. A spirit license, which used to cost 25*l*. and was afterwards reduced to 13*l*., may now be obtained for 2*l*. 10*s*. upon a 10*l*. house, and application may be made at any town where petty sessions are held; the effect of which has been to open the most wretched and fulsome abodes for the sale of spirits. These abodes become the haunts of persons of the lowest description and the worst of characters. The maintenance of so many dram-shops is chiefly owing to the ejected and broken-down farmers, who, unable to turn their time and labour to better account, dispose of what is left to them in the purchase of a stock of whiskey, trusting, for a market, to their country acquaintances and friends.

Various restrictions and regulations have been suggested to me, with the view of limiting the sale of whiskey. Its sale in grocers' shops was particularly objected to, as, by being removed from the fear of detection, the female servants who are sent to the shops become initiated into the habit of drinking spirits. The reduction of the price of tea and coffee was also recommended, as well as the introduction of a wholesome cheap malt liquor—a change which had, indeed, been effected with success in a few places; but, although it was felt that the substitution of beer for ardent spirits would conduce materially to the improvement of the health and comforts of the labouring classes, it had not been generally attempted, or it had fallen into disuse, upon the vague supposition that it tended to disagree with the ordinary potato diet of the people. The plea was, that potatoes required a more stimulating beverage, and whiskey, if taken in moderation, was useful in rousing the stomach and promoting digestion. The damp state of the climate was another equally erroneous excuse for preferring spirituous drink to malt liquor: and generally the poor have recourse to whiskey as a medicine in case of illness, and it is very difficult to persuade them of the mischief of such a practice. It is only the *bad liquor* *, according to them, which can do harm. By bad liquor is meant the adulteration of whiskey with deleterious substances, of which I was told a remarkable instance at Athlone, in the case of a boy, the son of a publican, who was destroyed by vitriol, which he had got at in the absence of his father. The publican acknowledged he kept it in the house for the purpose of mixing with the whiskey.

It is the common custom for a man to take his "morning" as it is termed, or glass of whiskey, before he goes to his daily labour. He feels disinclined, and indeed unfit to work till he has removed the vapidness and yearning of his stomach by a spirituous potation. The stimulus passing off after a while, recourse is had to a second and third dram, to appease the sensation of craving which is as constantly returning. In this way it is not long before the brain is made to feel the intoxicating effects of the spirit which has been imbibed in an empty state of the stomach, and a delirious excitement is produced. The constitutional susceptibility to this species of delirium is increased by the frequent habit of exciting it, and becoming at length confirmed, the patient is affected with a peculiar disease, which I cannot so well describe as by quoting the words of Surgeon Adams, of Dublin, through whose kindness I learned many interesting facts relating to this particular form of disease, and other effects which he had observed

* In proof of this, I may state what occurred to a medical officer at one of the Dublin hospitals. While dissuading some persons from dram-drinking, over the body of one of their friends who had fallen a victim to the cholera, he was interrupted, in the midst of his exhortation, by an old woman, exclaiming, "there, don't be blaming the whiskey; why sure it's the *bad liquor* that's doing it." The cry was caught up, and it was quite vain for him to attempt to say another syllable. It became a very general notion that whiskey, so far from being provocative of the cholera, was the best preservative against it; and drunkenness was never more prevalent than during the time the pestilence was raging.

produced by whiskey upon the general health and constitution of the poor of that city.

"Some abstain from whiskey for months together, and during this period they make a great sacrifice of comfort, and suffer the greatest privation in their own minds; they compensate themselves at the end of the fixed time by drinking for several days successively, or as they say themselves, 'successfully.' They thus produce a peculiar state of constitution, which makes them a prey to a species of delirium or fever, which in this country is well known by the name of whiskey-fever.

"This is characterized by the greatest apparent vivacity of mind and disposition. The patient sings and talks the whole day and night without intermission; says the most amusing things, betrays every secret he has, imagines he is riding or driving through the country, that he is pursued, or pursuing some ideal object. This state will last two or three days, during which the patient neither eats nor sleeps; he suffers no pain even when he has met with an accident, such as broken ribs; he will, regardless of any species of motion, (which, when free from this peculiar state, would cause him pain as if he were stabbed with a poniard), persevere in loud singing and vociferations: even when the subject of a compound fracture, he will get up and stagger across the ward while the broken leg is dangling about. At the end of two or three days it is usual for him to fall into a deep sleep, which lasts for 12, 16, or 20 hours, and then to awake well, but very weak.

"During the whole progress of this case real debility but apparent strength characterizes the complaint. There are nervous tremblings all over, cold clammy perspirations, and weak pulse. Whiskey, punch, and opium, in various forms are the proper remedies. A large bleeding sometimes had recourse to, so as to induce fainting, has in sundry cases produced death. The disease, in general, is got under for a time, and again recurs: sometimes, instead of sleep, after the excitement as described above has continued more or less time, the case terminates in convulsions, coma, and death.

"This nervous delirium, or whiskey-fever as we call it, is not confined to us. It is called 'vinomania' in France, and is known by the name of 'delirium-tremens' in other countries. Sometimes it is induced by a wound, or accident of some kind; but it very frequently comes on without such an exciting cause. What we term the predisposing cause is, an habitual indulgence to excess in ardent spirits. Men are generally the subjects of it, more rarely women, but even children are liable to it. I have been assured by one medical friend, that he has seen a child under ten years old affected by it.

"The effects of whiskey on the *idle* seem very fatal; the working-man bears a large quantity better. I have frequently known very laborious, yet whiskey-drinking men, earn by honest industry some little capital, and by such means become enabled to set up in business for themselves; and now continuing their former habit of drinking, while they cease to work as they were wont, they soon fall into ill health, lose all appetite for everything else, and live on whiskey alone. They usually die of diseased liver, consumption, or whiskey-fever. The small, shrivelled-up, hardened liver, called the scirrhous liver, or whiskey-liver, is generally found associated with dropsy. Organic diseases of the stomach and liver are the well-known consequences of dram-drinking in all countries.

"Immediate death is sometimes the consequence of a large potation at once of whiskey. Such cases as the following have been admitted into Jervis-street Hospital:—A man gets astride on a barrel, say at the Custom-House stores or docks, and by means of a straw inserted into the cask, sucks up whiskey in such a quantity that he falls down intoxicated, and soon becomes perfectly insensible, quite in an apoplectic state. If the tube of the stomach-pump be speedily introduced, and the whiskey drawn off, and aperient medicine sent down without withdrawing the tube, the patient recovers his consciousness, and rallies, if his case be judiciously managed; frequently, however, such patients die, either from want of due care or expeditious means being resorted to to get rid of the whiskey.

"By far the greater number of accidents admitted into Jervis-street Hospital, are either directly or indirectly the effects of whiskey-drinking. Drunken broils, domestic quarrels, while under the influence of spirituous liquor, are so frequent as scarcely to be worth mentioning. On Monday morning at the Dispensary women very commonly attend with cut heads, bruised faces, eyes encircled with black blood-marks,—a very common accompaniment to these are broken ribs. They are blooded, bandaged, and get some medicine, and return to their families, *forgiving* their husbands, at whose hands, in general, they have received the injury. *If the husbands were drunk*, they consider it an apology. Occasionally the women themselves are in fault, and men come to complain of having been beaten by their wives or other women. Injuries, however, of a much more serious nature, which have been caused by drunken quarrels, are frequently taken into the hospital. Thus, there have been four cases

of fatal stabbing within a short period. One of these, a wife, stabbed her husband (by whom she had four children) in the abdomen with a knife. The intestines protruded, and, although the best advice was immediately procured, the wounded man died of inflammation. In another case, two brothers, grown up and nearly of the same age, after drinking six days together, ended by quarrelling; one stabbed the other in the stomach — he vomited blood, and died in two days, although the best attendance was given him. Besides these cases there have been others of a fatal character from rupture of the intestines and bladder. They commonly occur in drunken broils, ending in a wrestling, or boxing match, between two of the party, when on falling the knee or elbow of the one does the injury which proves fatal to the other. I may add, that during all holiday times—about Christmas, the times of the fairs in the neighbourhood of Dublin—at these periods, the resident apothecary must be on the alert, and have his means in readiness for all accidents, as military surgeons make ready upon the eve of a battle."

CASE OF

RHINOPLASTIC OPERATION.

To the Editor of the Medical Gazette.

Sir,

I transmit to you the history of a case of rhinoplastic operation, for which, if you consider it sufficiently interesting, I hope you will find a place in your Gazette.—I am, sir,

Your obedient servant,

James Douglas.

Member of the Faculty of Physicians and Surgeons of Glasgow, Lecturer on Anatomy, and formerly House-Surgeon to the Glasgow Royal Infirmary.

93, Brunswick-Street, Glasgow,
27th May, 1836.

Agnes N., aged 25, was admitted into the Royal Infirmary, under Dr. M. S. Buchanan, August 26th, 1834, while I was his house-surgeon. She had been suffering from lupoid ulceration of the face for some months; there was an ulcer on the upper lip, and numerous cicatrices, while the soft parts of the nose were completely destroyed as high as the middle of the ossa nasi, leaving a horrible opening through which the septum nasi and inferior spongy bones were seen. She was not at all benefitted by her residence in the house, and left it in December. Having gone home, and given up the use of medicine, cicatrization at length took place, about the month of May. She remained much troubled with frontal headaches, and tendency to inflammation of her eyes, which symptoms I am inclined to attribute to the access of the cold air into the superior nasal fossa and frontal sinuses.

In February last, she consulted me on account of an attack of corneitis, which was soon subdued by calomel and opium, and informed me that she intended to get a new nose made, and that as she had been under my care in the infirmary, that she wished me to be the operator. Accordingly, on Sunday the 3d of April, I proceeded to the operation, with the assistance of my friend and former instructor, Dr. M. S. Buchanan, and in presence of Dr. Lawrie, Professor of Surgery in the Andersonian University, Mr. Macintyre, of Newcastle, Drs. Weir and Dick, of this city, and Dr. William M'Kenzie, of Paisley.

Having seated the patient in an arm chair, with her head supported by Dr. Lawrie, I commenced by paring the edges of the opening. Between the eyes the cut began by a transverse incision, half an inch in length, and below, over the middle of the upper lip, it finished by a transverse square wound, into which the columna nasi was to be inserted. I then laid upon the forehead the model, cut out of sticking-plaster, according to Dieffenbach's directions, about one-fourth larger than the estimated size of the new nose. As the columna extended as high as the hairy scalp, the hair was removed, and about a quarter of an inch of the scalp taken for the part of the columna to be fixed to the lip. The plaster was then circumscribed with the scalpel, and the flap dissected down off the pericranium. Where it terminated between the eyes it was about 5-8ths of an inch broad, and the cut on the left side was prolonged a little farther downward than on the right, to facilitate the turning of the flap. Three small vessels were tied, one where the columna was taken from, and a branch of each angular artery. An artery bled very freely in the flap, but was allowed to remain unsecured, as Dieffenbach advises. A good deal of annoyance was occasioned to the patient by the blood running in considerable quantity into the mouth from the nose.

About 6 oz. appeared to be lost. The oozing having ceased, and the parts been dried, the flap was twisted to the left, laid down, and fixed by twelve needles with the twisted suture, and three points of the interrupted suture. The wound on the forehead was brought together a little with adhesive strap and bandage, and a strip of oiled lint was introduced into each nostril, merely to keep them from adhering, and not so large as to produce distension. No other dressings were applied. She bore the operation well, which lasted nearly three quarters of an hour, the stitching proving very tedious. The nose was flaccid, and had assumed a livid colour throughout. In the evening it had begun to swell, and was somewhat red at the margins. She complained of little pain except in the forehead. To take 30 drops of laudanum.

Next day the nose was a good deal swollen and prominent, of a dusky red colour; no increased heat: slept pretty well. To repeat laudanum, and take physic in the morning.

3d day. — Nose rather better, and slight discoloration around two of the needles. A piece of lint dipped in oil was laid over the whole nose.

4th day.—Two needles removed, and the strips of lint in nostrils replaced by fresh ones. Perfect adhesion has taken place; wound on forehead suppurating kindly; oiled lint continued over nose.

5th day.—Some œdematous swelling around left eye; needles of left side removed, and their wounds bled freely. To take salts.

6th day.—Needles in right side and in columna removed; a strip of oiled lint laid along each line of union, and new dossils put into nostrils; œdema gone.

10th day.—A wash with chloride of lime was ordered to be injected into nostrils several times a day, as the smell was very disagreeable.

21st day. — Nose seems now cicatrized within, at least there is no discharge, and chlorine wash is dispensed with; all the swelling is now gone, and the integuments of the nose have a perfectly natural appearance. The twist in the flap at root of the nose lies perfectly flat, and will not require to be excised; it is so firm that she can take hold of it and blow it.

May 5th.—The nostrils having now contracted to about one-half their proper size, I proceeded to enlarge them. Incisions were made forward towards the point of the nose, forming in each nostril a small narrow flap, which was not wholly cut away, but left attached anteriorly. A long needle having been passed through both, above the columna, a ligature was twisted round it, also above the columna, and the flaps were thus drawn inwards to each other, and kept in apposition with the inside of the nose, previously made raw. Contraction will thus, according to Dieffenbach, be altogether prevented. In laying open the lower part of the nose it was observed, that there only existed a passage backward to the nares, and that the upper part of the nose is perfectly solid.

9th. — Adhesion of the little flaps having taken place, I wished to remedy the curvature downward of the columna, which had taken place in consequence of its thickening, and assuming a globular form. I therefore excised a small elliptical piece from its lower surface, and brought the edges together with two needles.

27th.—The result of the last paring has been satisfactory. The columna has ceased to curve downward, and the point of the nose is more elevated. The wound of the forehead is now healed to a point, (seven weeks after the operation) and would have been so sooner, but for a blow which it accidentally received. She never had the least constitutional disturbance, and has been attending to her ordinary avocations for the last month.

In conclusion I would only remark, that the operations for the restoration of the nose and lips when destroyed, have not received in this country the attention which they seem to merit. The covering from view such a disgusting deformity as a death's-head nose upon a living countenance would surely be meritorious, were the veil only a flat piece of skin: and the rhinoplastic operation certainly does not deserve the sneer with which it is treated by the author of a recent System of Surgery, whose reputation may unfortunately give too great currency to his opinion. I may add that my patient herself, and all her friends, are remarkably well pleased with the change which has been wrought on her; and that she is no longer troubled with the frontal headaches, or any inflammation of the eyes.

CASE OF SPASMODIC CHOLERA (?).

To the Editor of the Medical Gazette.

Sir,

I am not aware that any form of cholera has of late been prevalent. The following case may prove interesting, as showing that although this dreadful malady has ceased to exist as an epidemic, yet we may still occasionally find individual cases in which the symptoms are not far removed from spasmodic cholera in its worst form. Should you deem it worth inserting in your valuable journal, you will oblige, sir,

Your obedient humble servant,

Sam. J. Jeaffreson, M.D.

3, Norfolk street, Strand, May 30, 1836.

10 A.M.—A warehouseman, of about 50 years of age, with skin every where as cold as marble. Pulse too small to be counted; tongue furred. Voice scarcely perceptible; countenance cadaverous; bowels purged twelve or thirteen times within the last twelve hours; the dejections having exactly the appearance of rice macerated in boiling water, and without the slightest tinge of bile. The evacuations not copious, and I could not ascertain what had been their appearance at the first commencement of the attack. Has passed no urine; has only once vomited. *Frequent* and *painful* cramps, more especially of the legs. The abdomen, to the touch, felt contracted and hard, from muscular tension, but in no part tender on pressure. No distention of the bladder perceptible.

I learnt that he was a man of good general health, and temperate habits; but that his bowels were usually confined for some days together, and would then become loose for several days. Last night he ate a few radishes for his supper, which is the only cause he can suggest for his complaint.

A friend who had seen the patient about half an hour before myself, says that he was then of a very blue aspect. His face and hands were somewhat livid when I saw him, but not amounting to blue. My friend had ordered him—

℞ Calomel, gr. iij.; Opii, gr. iss. statim sum.; et ℞ Hydrarg. Submur. ℈j.; Opii, gr. j. M. ft. pil. xx. æquales quarum sumat j. quâq. semihorâ.

I recommended his repeating the pills with the following draught:—

℞ Sp. Ammon. Aromat. ʒss.; Sp. Ætheris Sulph. c. ♏xx.; Træ. Cardamom. c. ʒj.; Mist. Camphoræ, ℥xj. M. ft. haustus quâq. semihorâ, cum pil. (ut antea) sumend.

Mustard cataplasms to the calves of the legs, with hot water bottles to the feet, and warm sand bags to the abdomen, constituted the rest of his treatment. I also ordered a starch enema, with a drachm of laudanum, to be used, if the purging did not abate in the course of two hours.

7. *Vespere.*—Skin warm; pulse 100, very small, but steady; pills have only acted three times, and very slightly; dejections of the same nature as before. Cramps less frequent and severe; has passed urine; feels thirsty; tongue furred; expresses himself as "much better," and only complains "of feeling weak." The enema was not used.

Rep. Pil. et Haust. cui adde Liq. Opii sedativ. ♏vi. quâq. secundâ horâ.

2d.—Has had some comfortable sleep; pills have only acted once; evacuation of much the same appearance as heretofore, but coloured by bile. Has had hardly any return of cramps, and no reappearance of collapse.

Rep. Pil. et Haust. ter die tantummodo. To have some beef-tea.

Vespere.—Continues to improve.

On the 3d he had three motions from the bowels, containing feculent matter, and expressed himself as feeling nearly well: on the 4th he resumed his occupations, and has continued perfectly well up to the present time.

FEES FOR MEDICAL CERTIFICATES, IN EFFECTING POLICIES OF LIFE ASSURANCE.

To the Editor of the Medical Gazette.

Sir,

In the Gazette of the 21st instant, received this day, I find a very spirited leading article on the subject of "Life Insurance Policy Fees;" together with certain resolutions of the Glasgow faculty, well worthy of imitation by all grades of the profession in this country. The subject has been frequently discussed, I see, in the Gazette; the un-

fairness of the gratuitous certificate system has been fully shown, and the apathy of medical men equally demonstrated; otherwise I should have seen some *declaration* made by the metropolitan practitioners, in which we provincials would have readily joined. No such united effort has been made; and until it is, I beg leave to submit to your readers the plan I have acted upon for some years, in these matters; and which I advise them, for *self-protection*, to follow. It was attended with a little difficulty at first, but this was easily overcome; and I can assure you that the parties interested pay very readily for the service performed, and seem rather to value it more since they have been required to hand over the fee, than when it was done gratuitously.

I am frequently referred to, as a general practitioner, to furnish answers to a long string of questions respecting the state of health of my patients, by *three* parties. 1st, By the *officers* for whom I act as medical referee; for which, of course, I am *paid* the usual fee. 2dly, By the *parties themselves* who propose to insure their lives in offices for which I do not act as referee. 3dly, By persons who propose to insure the lives of *others*, as security for leasehold property, annuities, and so on. The payment by the two last classes was formerly of this sort:—"Sir, I am very much obliged to you, and any thing I can do to acknowledge the favour shall be readily effected." You made a polite bow in reply, and the parties disappeared. I began to reflect that all this was very foolish—that I was throwing away my time, and trouble, and professional experience, for no definitive object; that if I wanted any advice of my attorney, I was sure to be charged the usual ternary fraction of the pound sterling; and I came to the fixed resolution of making them *all* pay for the work done—that is, one or the other of the parties interested. I have put many pounds a year into my pocket by this resolution; and I do verily believe that I have *not lost a single patient* by doing so. When a *confidential* letter is sent to me from an agent of any other than my own offices, to be forwarded to town, or from any other person, I send it back again, with a polite note, to the effect, that *having laid down a general rule*, I cannot answer the queries proposed until I know by whom I may be paid my fee of *half a guinea* for the certificate, whether the insurance is effected or not. The agent communicates with the parties, and by the one or the other I am always paid. After a little time I had no need to send back the "confidential" letter: it was accompanied by the fee, or by a promise to pay it. They all know that they cannot get a certificate without it; and if it is their desire to insure, they will not be deterred by the medical fee, which I have fixed at 10*s.* 6*d.*—I am, sir,

Your constant reader,

Σ.

Truro, May 25, 1836.

LIFE ASSURANCE POLICIES.

REMUNERATION OF MEDICAL REFEREES.

To the Editor of the Medical Gazette.

Sir,

As you are once more engaged, in the last number of your journal, in advocating the right of the medical referee to receive a fee from the Insurance Office, I shall trouble you with a case which has recently occurred to myself, and with the name of the office concerned: and I do this the more readily because the case is peculiarly free from all imputation of private interest, both on the part of myself, and my patient whose life was insured.

The low rates of the Scottish Union Insurance Company (449, West Strand) had tempted some parties, in March last, to transfer to them an insurance from another office. It was necessary to continue the lives which had previously existed in the policy. These lives had no pecuniary interest whatever in the transaction, though the insurers doubtless sought for saving in their annual payments, and, I suppose, the Scottish Union Insurance Office intended to get an increase of profitable business transferred to themselves, on terms which they at least must consider to be advantageous. My friend continued his life to oblige all parties,—but a searching examination of health is not always pleasing, and particularly to a bachelor as he advances in years, and I considered my position in communicating with the office one of delicacy, which would not have been confided to a mere travelling *attaché* of the office. On former renewals of the lease, a fee had always been transmitted to the medical referee, and I cannot see any

reason why those who court business, and get it away from other hands, should be exonerated from paying a similar compliment to myself on the present occasion.—I am, sir,

Your obedient servant,

M.D.

May 24, 1836.

[The writer has given us his name and address.—Ed. Gaz.]

MEDICAL GAZETTE.

Saturday, June 4, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

Cicero.

ALIMENT AND POPULATION.

In our last number but one we alluded to the discussions which have lately taken place in various quarters as to the best means of maintaining a balance between population and the means of procuring sustenance. An important question it certainly is—for the bare idea of the number of human beings on the face of the earth exceeding what the available supplies of aliment are capable of supporting, conjures up a picture of no very agreeable kind. There are clearly two, and only two, kinds of expedient capable of being acted upon in such an emergency—namely, diminishing the population, or increasing the production of food. Some, indeed, have suggested a combination of the two—by which we were prepared to find the idea gravely revived of slaughtering the children for the sustenance of the parents, in the manner so happily suggested by Swift for diminishing poverty and starvation in Ireland; nevertheless we were mistaken in this, and found that the proposal was limited to the imposition of a "moral" and "healthful" check to the number of births—and to turning our attention to the "western world" for indefinite supplies of food.

That on the great scale any such disturbance of the equilibrium between the fruits of the earth and the number of beings with whom God replenishes it, exists, or is to be apprehended, we have never been able to make out, from the statements even of the hungriest of the economists; but that partial deficiencies of food, amounting even to destructive famines, may arise, is too well known to be denied, and too grave an evil to be disregarded.

The chief advantage, as it appears to us, which is likely to accrue from such discussions as the present, is that of ascertaining in what manner, and by what particular means, such visitations may be most effectually guarded against—or mitigated if they actually occur. We apprehend, indeed, that, in this country at least, too little consideration has been paid to the sources from which extra supplies of aliment may be procured in cases of emergency,—and to this it may not be uninteresting or unimportant briefly to direct attention.

Our distinguished countryman, M. Edwards of Paris, recently published some statistical researches on the employment of gelatine as an article of diet, from which it appears that our French neighbours are much beforehand with us in the theoretical investigation of this subject; nor, indeed, are they less so in its practical application—numerous establishments having been formed, in various parts of the country, at which large quantities of excellent soup have been made from materials which would otherwise have been nearly or altogether useless. Some, indeed, have endeavoured to throw discredit on the plan, and have expressed doubts as to the nutritive properties of the gelatine thus procured; but the evidence collected by M. Edwards*, in our opinion, sets the question at rest. This distin-

* Récherches statistiques sur l'emploi de la gelatine comme substance alimentaire.

guished physiologist has proved by experiments on the lower animals, by observations on man, and by extensive statistical investigations, that the gelatine obtained by any of the recognized processes from animal fibre and from bone is highly nutritious, and only requires the addition of a limited portion of other ingredients to render it agreeable to the taste and grateful to the stomach.

The method by which the gelatine is extracted from bones and the sinewy portions of meat, through the medium of heat and moisture, has long been known; and, improved according to the system adopted by M. Papin, is capable of forcing these intractable materials to yield a large portion of their nutritive principle. For this purpose a very elevated temperature is not necessary; and, indeed, one but little above the boiling point will be found to suffice. The process, however, we may remark, requires considerable care, as without this the *cooking* may be spoilt, and the soup rendered more or less ammoniacal. This was the case some time ago, at the Hôtel Dieu, in Paris; and the failure, or at least imperfection of the process, which was owing to the carelessness of those employed, was unfairly attributed to some defect in the principle itself. The plan employed in France is to use the solution of gelatine, procured from meat or bones for what, we believe, in the technical language of the kitchen, is called "stock." This is made into soup by the employment of one-fourth part of the meat which it is customary to employ in making soup with water merely. The addition of the small proportion of meat just mentioned is no doubt partly to communicate additional strength to the product, but is of more importance in rendering it sufficiently *aromatisée*. However, although meat in small quantity accomplishes this end most efficiently, yet it is not absolutely necessary, as occasionally a small portion of lard has been substituted with the best results.

If any one be disposed to think lightly of the benefits to humanity which such contrivances are capable of affording, we recommend to him to peruse the accounts which have been published of the transactions at Rheims a few years ago, where, after one of those civil commotions which disturbed the manufacturing towns of France, an immense number of unemployed operatives were reduced to the greatest misery, and to the most imminent danger of starvation. The municipal authorities, at the instigation of M. Commesny, established a soup manufactory. Strange to say, no complaint was heard even from those who were relieved; not only were the cravings of nature appeased, but the political phrensy of the people was subdued. As M. Edwards remarks, "On conçoit aussi qu'une nourriture aussi substantielle et savoureuse devait sauver la population souffrante, et la rendre satisfaite et paisible."

But besides the different forms of ebullition or digestion more or less calculated to obtain gelatine, another and very important method may be used to obtain it from bones. Ebullition, indeed, it is well known, will separate a certain portion from the hardest substances; and, accordingly, every cook knows the use of bones in making soup; yet does a very large portion of animal matter remain behind: now this may be separated from the earthy materials, or rather, the latter may be separated from the former, by means of acids. By this contrivance a very pure jelly is obtained, and one which has long been much used in France, particularly by the *restaurateurs*.

It is a very important principle, and one constantly to be kept in mind, that no simple elementary substance is capable by itself of sustaining the vigour of the animal body. Variety is not less neces-

sary to the taste than a certain degree of admixture is to efficient nutrition. Our readers will remember the experiment of Magendie, who, having fed rabbits on white sugar and distilled water, the creatures became cachectic, and the cornea of the eye ulcerated, suffering the humours of that organ to escape. This is also in keeping with the observations of Dr. Prout, who has well illustrated the principle (that combination within certain limits is necessary to nourishment) by quoting the example of milk, perhaps the only product of nature specifically intended for the purpose of aliment. Now this contains a variety of ingredients, particularly sugar, oil, and albumen. But experience has shewn, that though it be essential that a certain degree of variety in the constituents of nourishment should exist, yet but little is required to give to a good "stock" all that is necessary to render it sufficiently *aromatisé*.

Upon the whole, we cannot help thinking that if some of our Malthusean economists, instead of indulging in gloomy forebodings, were to turn the attention of the public to the best means of compelling the various substances around us to yield up the whole of their nutritive treasures, they would be much more usefully employed than they are at present. Bread has been made from the most intractable timber, and soup from the hardest bones; why, then, should we despond? True, the processes are not the simplest in the world, particularly with respect to the former; but herein is matter on which to exercise their ingenuity. To manufacture good and wholesome bread from wood, appears at first sight but a visionary proposal, and yet Dr. Authenreith has shewn that it may be accomplished; and the simplification of the requisite manipulation would certainly be a mighty attainment, even in these days of gigantic improvement. We have no doubt that a ready means of converting a tough sapling into the "staff of life," would go farther towards immortalizing the discoverer, even than the greatest among the triumphs of modern science. Increasing the supplies of aliment would also, it is presumed, prove quite as "moral and healthful" an antidote to over-population as any "preventive check" hitherto suggested.

THE INFLUENZA.

An epidemic catarrh, which it is the fashion to call influenza, has been, and is still, very prevalent in London. It consists in a slight inflammatory affection of the mucous membrane of the throat and air-passages, with coryza, painful deglutition, and cough. These local symptoms are generally accompanied by headache, and pain in the limbs, but more particularly by lassitude and depression, which in many are out of all proportion to the other symptoms. The complaint is evidently dependent upon the peculiar state of atmosphere engendered by a hot sun and cold easterly winds. Nothing more is required in the great majority of cases, than diaphoretics, gentle laxatives, and a few days' nursing.

CLINICAL LECTURE,

Delivered at the Westminster Hospital, Saturday, May 21, 1836,

By Mr. Guthrie.

SURGICAL ANECDOTES OF THE PENINSULAR WAR.

Contracted cicatrices — Amputation — Abandonment of the tourniquet — Improved mode of making the incision — Fallacy of the "compensation" principle — Inutility of flogging — Battle of Roliça — Original letter from the Duke of Wellington — Characters of Colonel Lake and Sir E. Packenham.

Three weeks ago you saw me relieve the neck of a poor little girl, 3 years of age, who had been burned, and whose lower lip was adhering to her breast. I removed the cicatrix; her head is kept up by a proper back-board and head-piece; and she will get well with as little deformity as can be avoided. These cases are

not common, but coincidences in surgery are not infrequent; and I have another of a similar kind at the bend of the arm, which prevents its being straightened. This girl is 13 years of age, and being the daughter of a person who has seen better days, I have put her under the care of the housekeeper of the Ophthalmic Hospital, and all of you who choose may be present at the operation on Monday.

You saw me a few weeks ago cut off the thigh of a child, 7 years of age, by the usual circular incisions. Poor Tommy! I tried very hard for weeks to save his leg, and even run it so close that I feared I was too late to save his life. The operation did however succeed; but he had a narrow escape. The child whose thigh I have just removed is 11 years old; the disease ulceration of the cartilages of the knee-joint, which he has had for months, and his mother brought him to me last week for the purpose of having it amputated. I did this by the flap operation on each side, so that you might have an opportunity of seeing the different methods of operating; for instances of the kind occur much too infrequently in our hospitals for the advantage of instruction, although quite frequently enough for the sake of the sufferers.

It is a proof of the advance surgery is continually making, for one operation is not performed now where three were formerly; and in many cases in which they were done commonly thirty years ago, they are not now even thought of. Sir Astley Cooper observed to me the other day, that the last war had given the greatest impulse to surgery it had ever received in this country; and there can be no doubt of the fact. Those who remained at home were obliged to labour and increase their knowledge, that they might be enabled to teach; and those who went abroad were obliged to learn, because they could not help it.

I have been the historian, or the recorder, of the Surgery of the Peninsular part of the War; and whatever deficiencies there may be in the record shall be completed. You have lately and on this day seen four of the improvements thus made.

1. I did not use a tourniquet, the screwing and unscrewing of which always creates some difficulty and annoyance. I never do when I have good assistants, but you must have recourse to it when alone, or when they are ignorant. A very moderate and simple pressure suffices to stop the flow of blood through the largest artery; and gentlemen who would have trembled forty years ago at cutting across the femoral or axillary arteries without an infinity of preparation, would now, if they were alive, cut either without the slightest hesitation. I never use one, to teach you confidence. I learned to do without a tourniquet from necessity, the mother it is said of invention, on the field of Vimiera, and I finally abandoned it at Albuhera (I beg, gentlemen, you will always spell Albuhera, when you have occasion to do so, with an *h*; you might as well write London without a *d*.) It was only, however, at the last battle of Toulouse the surgery of the British army approached perfection. There were even there one or two mistakes. Another campaign in the South of France would have made us perfect.

2. I always divide the skin and fascia by the first circular incision, down to the muscles; they will then retract with very little assistance, instead of the useless and painful dissection of the skin from the fascia, which formerly took place. This practice is, I believe, now universal.

3. You will find in books, that in dividing the muscles, you are to take particular care that you cut the long and unattached ones of a different length from those which are attached to the thigh bone, and each muscle according to its powers of retraction; so that they must be cut long and short, and of different lengths, something like the parts composing the compensation pendulum of a clock. I have no objection to all this; but I never saw it done, and have long since given up all thoughts of doing it myself; and why?—because I have seen scores of amputations done by all sorts of hackers, hewers, and bunglers, and I invariably found that no matter how they were hacked or hewed, whether the muscles were cut according to compensation principles or not, they always made capital stumps, when another rule was observed, viz. to cut the bone short, that is, to have it well covered by these same muscles and integuments. It is the golden rule of amputation, and the quicker you can do every thing else and come to that, the better for your patient. In the flap amputation, where all the parts are divided as nearly as possible at once, no attention can be paid to compensation cutting, and there is, therefore, no waste of time. Remember, therefore, always to cut your bone short—the stump may by this be one inch shorter than you could otherwise make it; but woe there is to the man, to the end of whose bone the cicatrix adheres, he is unhappy for the rest of his life—he will never forget his doctor.

4. Saw your bone perpendicularly, and not slantingly, which prevents its splintering.

I read, gentlemen, all the anecdotes, histories, and criticisms, which appear on the subject of the Peninsular war, with

great interest; sometimes I cannot help smiling at the want of accuracy which occurs as to time and place among the critics, and I have been half inclined to correct them, but doctors had better stick to their own work, and I shall only now and then give you a personal anecdote of some of my old friends, and after the lapse of so much time I may do it perhaps without the charge of vanity or presumption. You shall now have the first.

The action of Roliça (by the error of a copying clerk in Lord Bathurst's office miswritten *Roleia*, and absurdly continued) was an eventful day for many—for none more than for George Lake, the lieutenant-colonel commanding the 29th regiment. He fell at the moment of victory, and, as far as I know, no one has thought it right to record his worth. It is true an attempt has been made by Mr. Hamilton, in Cyril Thornton, to pourtray him as Colonel Grimshaw, and, however estimable he has made him, he was still a greater and a better man. In India he was early distinguished when serving with his father, the first Lord Lake, by his cool and determined bravery, his amenity of manners, his calm and gentlemanlike deportment. He joined the 29th regiment immediately before their embarkation, in 1807, under General Spencer, for Ceuta, and soon won the hearts of all. The officers adored, the soldiers revered, and there are few who would not have laid down their lives for him. The evening before the affair of Roliça, there was every reason to believe the regiment would be among the first troops engaged the next morning, and there were two bad subjects under sentence of a court-martial for petty plundering. It is to this hour the bane of the British army, that there is great difficulty in getting rid of men, upon whom neither precept, prayers, nor punishment, have any effect. There were at that time several in the regiment who had received from four to eight thousand lashes; they were incorrigible on some points, but most gallant soldiers. I think I see one of them now, poor Needham, a grenadier of the finest order of men, a fellow of the kindest heart, an excellent soldier, but he could not resist rum. In America, in summer or in winter—for heat or cold were nothing to him, he would swim the harbour of Halifax on a stormy night, and return to his post with as many bladders of rum tied round his neck as he could get money to buy. Of course every body got drunk, and poor Needham was detected and flogged; he never disputed the justice of his sentence, but as readily admitted that he could not possibly refrain from doing the same thing again. It was of no use flogging him; nevertheless, I saw him get the last of, I think, 18,000 lashes, without their being of the slightest use to him in the way of reformation. Indeed, I have seen many scores of thousands of lashes given, without being aware of any benefit being derived from them. It is of little consequence whether a man receives 100 or 300 lashes; my own opinion is, that he should receive neither: a brand is not affixed to a felon, and it should not be to a soldier. Nevertheless the British army must be occasionally flogged: it is mercy to the soldier to do it, and no discipline could be maintained before the enemy without it. In Great Britain, soldiers should be treated like wayward children, and no man, in my humble opinion, should receive more than two dozen lashes, and that on his bum, in the way schoolboys of 16 sometimes get it; and then, with their coats turned, they may be made to do their duty the same day, the derision of all the children in the town. An old culprit cares nothing whether he gets one hundred or five hundred lashes. I remember one of these gentlemen (Mr. Dennis Reardon by name), who, for some misdemeanor, was sentenced to receive 500 lashes. This the general commanding was pleased to commute for fourteen days' garrison black strap; that is, to work (or rather idle) fourteen days at the King's works, without 7d. a day: but Mr. Dennis declined the favour, and took the 500 lashes. Poor Needham died in the element he had so often braved with impunity. He was carried off the forecastle of a transport by a heavy sea, in the Bay of Biscay, and was long seen buffetting the waves in vain, and without hope or prospect of relief. He was the *beau ideal* of a grenadier.

Colonel Lake, when he formed his regiment in the evening for the punishment of the two culprits, knew full well that every man was satisfied they deserved it, but he did not say that. He spoke to the hearts of his soldiers; he told them he flogged these men not alone because they deserved it, but that he might deprive them of the honour of going into action with their comrades in the morning, and that he might not prevent the guard who was stationed over them from participating in it. The regiment was in much too high a state of discipline to admit of a word being said, but they were repeated all the evening from mouth to mouth; and the poor fellows who were flogged declared to me they would willingly, on their knees at his feet if they dared, have begged, as the greatest favour he could bestow, to be allowed to run the risk of being shot first, with the certainty of being flogged afterwards if they escaped.

Early the next day we came up with the French, drawn up in line, with the

village of Columbeira on the rear of their left, the heights of Roliça Columbeira, or Zambugeira, as they are indifferently called, behind, and covering the main road which turned the right of their position. They were the two battalions of the French 70th regiment, and the 29th and 82d advanced in line to meet them. A line of two deep, either for attack or defence, is peculiar to the British; all other nations attack in column, but British disciplined troops can do what none others can do, and no day of ordinary parade could appear more beautiful than this. We advanced in this manner in perfect order and in ordinary time with shouldered arms, until the red tufts, nay, the very faces, of the French line could be distinguished. Lake and his horse seemed both to be prancing with delight. I was told my place, on such occasions, was seven paces in the rear of the colours (we then knew no better), and he seemed to be about as much in front. At this moment he turned round, calling out, "Gentlemen, display the colours." The colours flew, the horse and he had another prance, when he turned again and addressed the line:—"Soldiers, I shall remain in front of you, and remember that the bayonet is the only weapon for a British soldier." The French at this instant retired, and the right of the 29th meeting the road, broke into sections and following through the village of Columbeira. One field separates the last houses of the village from the foot of the heights which rise almost perpendicularly above it. A narrow ravine seemed the only accessible part, and up this, Lake, without hesitation, led his grenadiers on horseback. The whole regiment followed, with unexampled devotion and heroism, and gained the summit; but not without the loss of 300 men in the desperate conflict, which took place almost hand to hand, in the olive grove half way up the hill. Broken and overpowered by numbers, Lake fell, and his soldiers would have been driven down, if the 9th regiment had not rushed up with equal ardour, led by a no less gallant soldier, Colonel Stewart. The two regiments formed on the crown of the hills, supported on their right by the 5th, which had been less opposed, and the French retired, finding that their right was by this time turned. Colonel Lake, on horseback, on the top of the hill, seemed to have a charmed life. One French officer, of the name of Bellegarde, said afterwards, that he had fired seven shots at him. Once he seemed to stagger as if hit, but it was only at the seventh shot he fell. It is probable he was right, for he was wounded in the back of the neck slightly; but the ball which killed him passed quite through from side to side, beneath the arms. I think he must have fallen dead. Will you permit me to record the end of as brave, although an humbler soldier? The sergeant-major, Richards, seeing his colonel fall, stood over him like another Ajax, until he himself fell wounded in thirteen places by shot and bayonet. I gave him some water in his dying moments, and his last words were, "I should have died happy, if our gallant colonel had been spared;" words that were reiterated by almost every wounded man.

Colonel Stewart, who led the 9th, fell also. He was struck by a musket-ball in the belly, which lodged; I saw him a short time afterwards lying under a myrtle-bush, and he beckoned me to come to him. "Our friend Brown," said he, meaning the surgeon of the 9th, "gives me no hope, pray look at me." I did so, and he saw I had none to give either. He thanked me, and begged he might not detain me from others to whom I could give relief. He died, poor fellow! a few hours after, with the resignation of a christian, and the firmness of a soldier.

I have been led to be thus garrulous, from having obtained, only the day before yesterday, a copy of the letter addressed by the Duke of Wellington, then Sir A. Wellesley, to Sir Richard Borough, who had married Colonel Lake's sister. It is the letter of a soldier, announcing and regretting the loss of another, for whom he had a firm and affectionate regard. I cannot resist reading it to you.

Lieutenant-General the Hon. Sir A. Wellesley, K. B., to R. Borough, Esq.

"Lourinha, 18th August, 1808.

"My dear Borough,

"I do not recollect the occasion upon which I have written with more pain to myself, than I do at present to communicate to you the death of your gallant brother-in-law. He fell in the attack of a pass in the mountains, at the head of his regiment, the admiration of the whole army; and there is nothing to be regretted in his death, excepting the untimely moment at which it has afflicted his family, and has deprived the public of the services of an officer who would have been an ornament to his profession, and an honor to his country.

"It may at the moment increase the regret of those who lose a near and dear relation, to learn that he deserved and enjoyed the respect and affections of the world at large, and particularly of the profession to which he belonged; but I am convinced, that however acute may be the sensations which it may at first occasion, it must in the end be satisfactory

to the family of such a man as Colonel Lake, to know that he was respected and loved by the whole army, and that he fell, alas! with many others, in the achievement of one of the most heroic actions that have been performed by the British army. I cannot desire to be remembered to Mrs. Borough, but I beg you to believe me, &c.

"ARTHUR WELLESLEY.

"To R. Borough, Esq."

I know no man of those who are no more, who can be compared with Lake, except Sir E. Pakenham. I have always a pleasure in bringing them to my recollection. I can fancy them as I last saw them before me: alike noble and generous in their natures, as incapable of fear as of doing a bad action, they were never so happy as in doing a good one: equally devoted to the fair sex, they were in all situations when they called upon them, their willing guardians and protectors: they were the Bayards of the British army. Sir E. Pakenham was never so animated as before the enemy: the sound of a shot seemed to give him the greatest delight; he snorted at it like a racer on the course; and, like Lake, he was always the first in danger, and the last out of it. Careless of themselves, considerate for others, wounded on several occasions, they seemed to forget that such a thing could again occur. His regard for the Duke of Wellington was unbounded. When the British army retired before Marshal Marmont, from Fuente Guinaldo, and maintained its ground on the heights near the Convent of Sacca Parte, in front of Sabugal, he thought the Duke, he told me, was needlessly exposing himself, and prevailed upon him to fall back a little. We had scarcely done so when one cannon-shot killed an officer of the 23d Fusiliers, close to him, and another struck the ground at his feet. The Duke merely turned and said, "Pakenham, this is what you call taking care of yourself." In his illness at Madrid, his anxiety for the Duke and the army at Burgos prevented his recovery. I was the chief of my own branch of that army, amounting to more than 30,000 men, under my Lord Hill; and for ourselves we had no apprehension. We could have beaten Marshal Soult any day in four hours, who had about our own numbers, but we flattered ourselves of inferior troops; there was, however, no advantage to be gained by beating him at Madrid, if our communication was cut off at Salamanca. He only began to recover in the retreat, when there was nothing to think of but fighting.

At a later period, in the fierce conflicts in front of Vittoria, he lost a friend, an officer of his old regiment the Fusiliers, Lieut.-Col. Despard, who was killed by a ball which lodged in his back-bone. His widow arrived some time afterwards at St. Ander, with four children, from Lisbon, alike wanting in friends, and, in a foreign country, of means. Sir E. Pakenham sent me a hundred pounds for her use, desiring me to say it came from a fund in the regiment, to which she was entitled without any sort of favour, on account of her children. Spare, he said, at all hazards her feelings; they will be greatly hurt if it is offered as a present from me, and will be refused; and be assured you will not be telling an untruth, for I consider every farthing I have to spare as a fund entirely at the service of every widow and orphan of that regiment. She does not to this hour know that the money came from Sir E. Pakenham. One of these four children was his godson. He has been now near fifteen years a lieutenant, and returned two years ago from the West Indies, his health ruined, his constitution almost destroyed. He has no prospect but a return there in autumn, unless the paternal kindness of the Commander-in-Chief shall relieve him from a fate differing from his father's only in being more untimely and inglorious. England, magnificent in her wealth, splendid in her extravagancies, deals only with her brave defenders with a niggard hand; to all others she is just, if she cannot always be generous.

I parted with Sir E. Pakenham at Lord Dartmouth's door, at the corner of St. James's Square, the day he started for his last command. On shaking hands, I said, "We part now for the last time; I shall never see you again." He asked, "Why say so; what makes you a prophet of evil?" I replied, "I know you so well, that I feel confident you will not be able to hear the first shots fired without being in the affray; and you will be killed, I fear, foolishly." He knew the object I had in saying this, the feeling that dictated it, and, in pressing my hand more warmly, he said, "That I shall fall, is possible; but if I do, you even shall say I fell as a general, commanding in chief, ought to do." When his aide-de-camp, Colonel Wyly, returned to England, he dined with me alone, that we might talk over the last acts of the life of our departed friend. In the front of a regiment which appeared to be failing in its duty, on horseback, with his hat off, he received his first wound. Feeling that he could not sit his horse, he endeavoured to dismount. In the act of lifting his right leg over the saddle, a second shot struck him a little above the groin, and, it was afterwards found, had divided the great iliac

artery. He fell dead, and he kept his word.

We will, gentlemen, at some future day, continue our observations on the advance of surgery in the war of the Peninsula.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Pathological and Surgical Observations relating to Injuries of the Spinal Cord. By Sir Benjamin C. Brodie, Bart., F.R.S., &c.

The paper of which the above is the title is an exceedingly elaborate and valuable essay, of which it is impossible for us to give more than an outline.

Sir Benjamin began by observing, that as the brain and spinal cord were analogous in anatomical structure, it was to be supposed that they would bear a resemblance in the effects produced upon them by injuries; and this circumstance seems to have led to writers generally limiting their observations almost entirely to the head, leaving the affections of the spine to follow as matter of inference. The object of the present paper is to supply in some degree the deficiency thus produced.

Wounds penetrating the spinal cord are generally fatal within a very short period; and Sir Benjamin professed to have nothing new to offer regarding them, but referred to the work of M. Ollivier for some interesting experiments connected with the subject.

The other kinds of injury were arranged as follows:—1. Fractures of the vertebræ, without displacement of the fractured surfaces. 2. Fracture with depression or displacement of bone, so as to diminish the diameter of the spinal canal, and occasion pressure on the cord. 3. Fractures complicated with dislocation. 4. Dislocations not complicated with fracture. 5. Extravasations of blood on the surface of the membranes of the spinal cord. 6. A clot of blood extravasated within the substance of the spinal cord. 7. Laceration of the spinal cord and its membranes; and this may be partial or complete, or modified in various other respects. 8. The minute organization of the spinal cord may be injured from a blow, even where there is neither fracture nor dislocation. In such cases, the cord, if examined at an early period, is found to be softened in the centre,—and this change at a later period becomes perceptible in the whole diameter of the cord—occupying one, two, or more inches—and, in more advanced cases, the complete dissolution of the cord may have been accomplished.

Sir Benjamin alluded to the remarks which he made in his paper on Injuries of the Brain, in the 14th volume of the Transactions, and shewed that the same reasoning applies to the spinal cord, with this difference, that the symptoms during life are more severe, and the changes found after death more conspicuous: a circumstance which the author attributed in great measure to this—that the brain does, and the spinal cord does not, completely fill its bony investment,—by which arrangement of course the latter is more apt to suffer from violence applied to it.

The symptoms accompanying an injury of the spine may be referred to—1. concussion; 2. laceration; 3. pressure; 4. inflammation; and 5. other organs not originally affected may suffer secondarily.

Paralysis.—Paralysis takes place below the injury, and may be partial or complete, according to the extent of injury. The paralysis also varies in other respects, particularly in cases of concussion. Thus the patient may be able to use the limbs in the recumbent posture, though he cannot stand, &c. Sometimes the paralysis, at first complete, gradually diminishes; sometimes the reverse happens. In injuries of the spine the lower limbs are frequently paralysed, without the upper being affected; whereas in caries of the cervical vertebræ, the upper limbs are occasionally paralysed for weeks or months before the lower limbs participate in the loss of power. Sir Benjamin, however, has seen a case in which a contusion of the middle dorsal vertebra was followed by palsy of the upper extremities, and Mr. Stafford has related a similar case.

Paralysis from an injury of the spine is of course very formidable, but the author stated, nevertheless, that he had known many instances in which the parties recovered to a greater or less extent; and numerous cases were referred to in illustration.

Spasms.—Spasmodic affections sometimes occur after injuries of the spine; Sir Benjamin thinks that they depend on pressure, having never seen them where this was not found to have existed.

Sensation.—If an injury be inflicted in the region of the sixth or seventh cervical vertebra, the destruction of sensibility is complete in the lower limbs and trunk, but only partial in the upper extremities; but if the injury be above these, the head only retains its sensibility, and the patient lives for a time quite unconscious of the existence of his limbs or body.

The lesions of sensibility are not less various than those of motion; sometimes the loss is complete, sometimes partial; sometimes the patient experiences some unusual sensation. Sometimes the loss of sensibility is complete in the first in-

stance, and gradually subsides; in other instances just the reverse takes place.

Respiration.—Division or laceration of the cord above the origin of the phrenic nerves causes immediate death, owing to the muscles of respiration no longer receiving nervous influence. Life, however, may be prolonged for a limited period, by artificial respiration.

Pressure at the upper part of the cord from dislocation, is usually, but not invariably, followed by speedy death.

When the injury takes place below the origin of the phrenic nerve, in the neck or upper part of the back, the diaphragm continues to act, the other respiratory muscles being paralysed, and in this case the act of expiration is but imperfectly performed. The lower down in the spine the injury is inflicted, the less is respiration affected; nevertheless, if the injury be high enough to involve the nerves going to the abdominal muscles, these, by becoming paralysed, render expiration less energetic.

Priapism is a very frequent symptom in injuries of the spine; but Sir Benjamin has never known it occur, except in combination with paralysis. It is independent of any sensibility of the parts, and may result from the irritation of introducing the catheter, though the patient be perfectly unaware of the operation.

Urinary Organs.—The bladder is paralysed, and the patient is wholly or partially unconscious of its distention. This symptom is one which supervenes at an early period of the injury, and in fatal cases, remains throughout.

It is not uncommon, immediately after the accident, to have a diminution in the quantity of urine, particularly if respiration be much impaired. Sometimes the urine first secreted is acid, with an offensive smell, but without mucus; sometimes it deposits a yellow amorphous sediment; but the most common phenomenon is for the urine to be turbid, with an ammoniacal odour, and copious deposit of alkaline mucus. In this last the phosphate of lime is after a time perceptible: there is a tinge of blood, and afterwards an admixture of this in a state of coagulation. These symptoms generally come on in a few days, sometimes they continue for weeks or months; sometimes they subside, and the urine again becomes acid. Occasionally the acid and alkaline states of the secretion alternate.

The mucous membrane lining the bladder and urinary passages frequently becomes inflamed.

Digestive Organs.—The bowels are torpid, and in fatal cases generally tympanitic; the intestinal contents are voided unconsciously. Where the injury is in the cervical spine, there is often a disposition to vomit;—such cases are generally speedily fatal. The matters evacuated are often dark; but the circumstance on which this change of colour depends has not been ascertained.

Temperature.—Injury of the upper part of the spinal cord gives rise to a remarkable evolution of temperature; this has been ascertained by experiments on the lower animals, and the author has seen it in the human subject. In a patient at St. George's Hospital, with injury of the cervical vertebræ, the heat rose to 111°, at a time when the respirations did not exceed five or six in a minute. Some farther light is thrown on this subject by the result of Sir Benjamin's experiments, which shew that the development of heat is not in proportion to the consumption of oxygen.

Gangrene.—The vital powers of the parts below the injury are diminished, and one manifestation of this consists in the facility with which they run into gangrene, from slight pressure. Sloughs may even begin to form so early as the second day.

Sensorium.—Derangement of this takes place immediately after, and as a direct result of, the accident, chiefly in injuries of the cervical spine. They vary considerrably.

Other symptoms.—The force of the circulation is diminished, and a state of collapse induced. In severe cases the patient may die without any reaction; and even in less violent injuries the heart's action remains impaired, though the frequency may exceed the natural standard. The tongue becomes dry, brown, and then black. The blood, if drawn, usually exhibits a large loose coagulum, with little or no buff. These phenomena are connected, in the opinion of the author, with the process leading to softening of the cord, and which he holds to be essentially different from inflammation.

Inflammation of the investing membranes of the spinal cord is by no means so frequent as of the membranes of the brain.

In reviewing the effects produced by injuries of the spine, one remarkable fact alluded to by Sir Benjamin, was, that the effects are nearly the same, whether the cord be lacerated or compressed, or softened; and farther, the majority of the symptoms are the same, whatever part of the cord is injured. Indeed, there seems to be but one symptom, or set of symptoms, with regard to which much difference is manifested, according to the seat of the injury—viz. those connected with respiration, as has been stated above.

Examples of recovery from injuries of the spine which have appeared very formidable, are by no means uncommon.

Treatment.—If there be displacement of bone, ought any attempt to be made to reduce it? The circumstances warranting such proceeding, in regard to the neck, must be extremely rare; but in the lower part of the spine it may be successfully accomplished; in proof of which, Sir Benjamin referred to a patient, in whom Mr. Hardwicke, of Epsom, had reduced a displaced vertebra (the first lumbar), the return of the bone taking place, as was described, with a "jerk, or snap." In another case, where there was great displacement of the third and fourth lumbar vertebræ, Sir Benjamin partially effected their reduction.

Mr. Henry Cline proposed the application of the trephine, in cases of fracture of the spine, with depression; upon which operation Sir Benjamin made some remarks, to the effect, that the cases in which the question can be entertained are extremely rare; and even in them it must be doubtful whether harm may not result.

Complete repose is the most useful expedient in injuries of the spine: the patient is to be laid supine and horizontally on a mattress.

When inflammation comes on, the patient must be bled, as in other inflammations. But in the majority of cases the chief evil to be apprehended is softening,—a condition which Sir Benjamin thinks hurried on, rather than retarded, by venesection. Purgatives are required, and the author has found ammonia a very useful addition in facilitating their action. The catheter must be used, and the more frequently, the more disposition there is to alkaline urine and adhesive mucus: this last sometimes requires to be washed out with injections of tepid water.

We conclude this brief notice with a very important remark made by Sir Benjamin—namely, that much harm has resulted from the application, *to injuries of the spine*, of the principles and practice proper in *injuries of the head*.

ROYAL INSTITUTION.

Friday, May 27, 1836.

Unrolling of a Mummy.

If there be any thing with which the public have become perfectly familiar of late, thanks to these "piping times of peace," it is with the unrolling of mummies. It is as common as dining. Yet, as people, when they come to dine together, especially in public, hate long graces, and would feel mortally provoked if the chairman, instead of proceeding to business, were to waste their time in giving an account of dinners in general, and of what they were likely to find on the dishes before them in particular, when the covers should be removed, so was a large audience indignant on the present occasion; having assembled to feast (their eyes) on "a very fine mummy," and finding their appetite completely spoiled by the grand carver, Mr. Pettigrew, who persisted in holding forth for two hours on mummies generally, before he could be persuaded to let the prime dish be touched. The truth is, that Mr. P. got astride of his hobby-horse, and was anxious to shew before a large audience how well he could ride. Tristram Shandy, indeed, advises, that "as long as a man rides his hobby-horse peaceably and quietly along the king's highway, and neither compels you or me to get up behind him," he ought not to be interfered with. But Mr. P. wanted to take all the world up behind him, and grew angry at last because the spectators did not like the performance just as well as himself. For two mortal hours Mr. Pettigrew held forth on hieroglyphics, embalming, and mummification, telling his audience every thing that he had often told them before (we have ourselves heard him now on three occasions); and he would have gone on for another hour, that is to say, *till midnight*, had he not been positively refused a hearing: he was good-humouredly laughed into order by the assembly, which had too long listened to his irrelevant "observations" with patience.

The mummy, when it at length came to be examined, proved to be really a very fine one—fresh as if it had been manufactured only last week, and had never slept among the Pharaohs. It was purchased at the late Mr. Salt's sale. Among the company present to witness Mr. Pettigrew's performances, were Lord Prudhoe, Mr. Wilkinson, Professor Leyman, of Leyden, and a number of other connoisseurs in mummies: we fear they were not much compensated for their trouble in attending, for we believe there was nothing in any way remarkable discovered.

INDIAN HOSPITAL REPORTS.

Hospital Practice in the Hospital of the Second or Queen's Royal Regiment, Calcutta.

By Mr. Hunter.

Aneurism of the Aorta.

P. Cunningham, æt. 30, admitted 18th February, 1835. Pain in the left chest, dyspnœa, and cough; expectoration scanty and pituitous; apyrexia; pulse 88, full

and soft. Respiration high anteriorly; low sibilous rale under left clavicle.

V. S. ad ℥x. &c. &c.

19th.—Much relieved; pulse 80, soft. Respiration high, and bronchial under both clavicles. Puerile in left subscapular region. Obscure in right, occasionally with thin mucous rale. Percussion, no result.

Diagnosis. — Dry catarrh (Laennec). Again bled to 12 oz. on the 22d, and transferred to convalescent ward on the 2d of March. Respiration nearly natural, and pain gone.

April 8th.—Re-admitted from convalescent ward. Pain under upper portion of sternum, dyspnœa, and cough. Apyrexia; pulse 76, moderate. Respiration high over all the chest. Heart's sounds, impulse, and rhythm, natural.

10th.—Dyspnœa urgent all night, obliging him to sit up in bed. No expectoration; pulse 70, moderate. V. S. &c. &c.

12th.—Relieved by the bleeding. Dyspnœa again urgent. Only easy when sitting up in bed, with his head and shoulders bent forward. Cough, with scanty pituitous expectoration. Pulse 92, moderate.

May 2d.—Stuffing under upper portion of sternum, and rattling in his throat. Respiration over the part sonorous, but without rale. Apyrexia; pulse 68.

8th.—Tolerably well. Transferred to convalescent ward, and to be invalided.

June 27th.—Re-admitted. Sits up in bed, but dyspnœa not very urgent. Pulse 60, weak. Respiration sonorous in right subscapular and interscapular regions; elsewhere scarcely audible. Rattling in throat distinct to by-standers.

28th.—Dyspnœa very urgent all night. Respiratory muscles in strong action. Loud sonorous respiration over lower portion of trachea, like the prolonged sound of a steam-engine. The chest as yesterday.

Diagnosis.—Contraction of lower portion of trachea, from thickening of its lining membrane (tracheitis).

July 2d.—Is obliged constantly to sit up. Pain in left shoulder in the night. Tolerably easy during the day. Apyrexia. Pulse 80, moderate. Sonorous respiration confined to trachea. Respiratory muscles in strong action. Murmur in chest very indistinct.

5th.—Respiration high and clear over all the chest anteriorly; over trachea, highly sonorous. Heart's pulsations weak.

Diagnosis. — Heart and lungs healthy. Disease confined to trachea and perhaps large bronchi.

12th.—Soreness betwixt his shoulders; dyspnœa and rattling in his throat; pulse 88, moderate.

17th.—Pain under left nipple; thinks, but for that, he could now lie down.

V. S. ad ℥vi. &c. &c.

18th.—Blood cupped, and sizy. Pain removed. Respiratory murmur only very partially heard in chest since 5th inst., though both abdominal and thoracic muscles have always been in powerful action. Sonorous (engine) respiration over lower portion of trachea. Pulse 92, small.

21st.—Became rather suddenly worse towards morning. Now sitting up, his head and shoulders bent forward, scarcely able to breathe. Lips pale, surface cold. Pulse 80, occasionally indistinct——Died at 1 P. M. ——Marked in a note previous to examination,—'Suffocation from contraction of lower portion of trachea, from thickening of its lining membrane, or the pressure of a tumor from without.'——*Autopsy.*—True aneurism of aorta (right side) from immediately above valves to beyond origin of innominata. False sacculated aneurism from this, of the size of two oranges placed together, ascending behind sternum and impacted betwixt upper portion of that bone and trachea. Heart and lungs perfectly healthy, as were all the bronchial tubes and trachea, except a greater degree of redness at the part on which the aneurism was resting.

Remarks.—Where was the aneurismal sound and impulse? No doubt under the upper portion of sternum; but we were too easily satisfied, and perhaps as his chest was very thinly covered, were contented with applying the stethoscope over the softer parts, where it was more easily adjusted. The stethoscopic signs, &c., indicated obstruction to the free entrance of air into the lungs, and the expectoration, though scanty, was that of bronchitis—consequently bronchitis, and the obstruction caused by congestion or thickening of the bronchial membrane. We quite forgot the snoring and sibilous rales of bronchitis, but then this was the *dry* catarrh of Laennec, never thinking these depended on this very state. Had there been a free secretion, we should also have had the mucous rale. The low sibilous rale under left clavicle, and the thin mucous in right chest, at first assisted in leading us astray, but we ought to have seen they were too insignificant. They are now easily accounted for. Afterwards, when called to the immediate seat of the disease, nothing but the previous impression could have prevented the detection of aneurism, but with bronchitis on our minds, what was more possible than the disease to have more particularly affected the trachea and large bronchi? Even the clear respiratory murmur on the 5th July did not surprise us, for the disease had already

been marked, tracheitis. Its sudden appearance and disappearance might have convinced us that the obstruction could not have been of any permanent nature. Pressure of a tumor was ultimately suspected, but whether then an original or only revived idea, it would be now difficult to say. Aneurism we never dreamt of till just prior to the post-mortem examination, and then only as a possibility. It is evident, however, the most correct diagnosis could not have materially affected the result, and therefore it is a cheap as well as valuable lesson. It would be well, perhaps, to trace the course of the aorta in all pectoral affections, though it must be confessed a regimental medical officer cannot always give such a degree of attention to minor cases.

Pectoral Disease.

John Carty, æt. 31, 10 years in India. 15th June, 1835. Has been frequently in hospital with pectoral symptoms for a year past. Lost his voice in January last, and has never since recovered it. Admitted on the 2d instant with pain and stuffing in his chest, the former, particularly in left side, extending to left shoulder, dyspnœa and cough, with some expectoration of phlegm. These symptoms, though again considerably relieved, are by no means removed. Speaks in a kind of croaking whisper. Apyrexia. Pulse 76, equal at both wrists. Sleeps badly. Decubitus on back; lying on right side causes dragging sensation in the left chest; and lying on left increases the pain of that shoulder. *Physical signs.* Left 2nd, 3rd, and 4th cartilages curved downwards, and more prominent than right. Chest resonant, except over lower thirds of sternum (perhaps some deficiency also in left subclavian region, though not very evident).

Respiration louder (distressed) over all left chest anteriorly, even in cardiac region, than in right. Somewhat sonorous under clavicle, but without rale. Heart's sounds and rhythm natural. Sounds very distinct in right subclavian region. Diastole audible in left, but systole marked by bellows murmur. Bellows murmur also audible above left clavicle; in axilla, and in lower part of left interscapular region, but at present nearly confined to these. Impulse evident under clavicle near sternal junction, greater than in any part of cardiac region, but I think more appreciable without the stopper.

Diagnosis.—Sacculated aneurism of aorta, compressing the left lung and bronchi, and throwing the heart to the right of its natural situation.

Prognosis.—Most probably sudden death. Time very uncertain. Within 12 months.

Remarks. — Here we have the signs which we overlooked in the last. But for these, all we could have said would have been, that there was disordered function of left lung; or, from the general symptoms, we would have termed the disease pneumonia, knowing nothing of the matter. With the aneurismal sound and impulse, however, the history of the case, the loss of voice, the distressed respiration of left lung, with permeable state of both, and the situation of heart, are easily explained; and instead of now creating difficulty, all tend to confirm the diagnosis.

On the Retention of the Placenta.

Having lately observed in your valuable journal, one or two notices of the successful use of Ergot of Rye in the retenof the placenta, and impressed with a sense of the danger of trusting to medicine where the retention has been of much more than an hour's continuance, or where any untoward symptom is present, I am induced to subjoin the following, to bring the more efficient means conspicuously into view.

B. C.—ætat 28, the mother of several children. Had a miscarriage in the fourth month, three days previous to admission; brought to hospital at 9 A.M. in an almost continual state of syncope from uterine hemorrhage, supposed owing to retention of the placenta, that not having been positively ascertained to have come away, though the cord had the first night. An enema of 2 oz. of gruel, and a drachm of laudanum, having been administered, I immediately commenced to open the os uteri, by first insinuating one finger, then two, and so on, gradually dilating it from within outwards, and occasionally resting, to imitate natural pains. From the exhausted state of the patient, the dilatation was soon accomplished, and the placenta laid hold of, but still it could not be brought away till the hand was introduced, when a small portion of it was found grasped by a contraction in the fundus uteri. Into this contraction the fore-finger was insinuated, and the placenta liberated by drawing the finger two or three times firmly along its surface. The fingers were then moved gently round the womb till it firmly contracted, expelling its contents. Scarcely any blood was lost during the operation, perhaps partly owing to the exhausted state of the patient, but I think chiefly to the permanent stimulus of the fingers. It was such an extreme case, that I think but for Mr. Wilkins, of H. M. 4th Light Dragoons (then acting surgeon of the regiment), I should not have had courage to have gone on with it. Just before the hand was introduced she was for some se-

conds supposed actually dead. It is unnecessary to add, we had to make liberal use of spirits, &c. both during the operation, and for several hours after. In the evening, however, the pulse had become quite distinct, and she afterwards recovered without a single unfavourable symptom. While on this subject, I may mention we had a case where the placenta was expelled before the fœtus; but knowing it was not the first instance of the kind, I kept no notes of it. If I recollect right, she had uterine hæmorrhage for some days previous, but not alarming till the morning of admission.

I may also mention, I have tried the stethoscope in three cases of pregnancy: one in the sixth month, and the others in the eighth and ninth respectively. In all the sounds of the heart and placental arteries were very distinct. In the first, the sound of the heart exactly resembled the fast ticking of a watch, and seemed, as it were, to rise sometimes close to the ear, and then again sink to a distance.

In the others, the sound was softer, more distinctly double, and fixed. In the first the pulse was at 140; in the second, 136; and the third, 144, more easily numbered than the pulse at the wrist. The impulse of the child, too, was very distinct at times, and by no means agreeable to the ear, when listening for a low and distant sound. I have no doubt, Mr. Editor, you will agree with me in saying, that were it for pregnancy alone, the value of the stethoscope is incalculable.—*Indian Journal of Medical Science*, Dec. 1835.

METROPOLITAN UNIVERSITY.

The steps recently taken by the College of Physicians have given a stimulus to the framers of the new Metropolitan University; and we understand that the announcement of its completion may be immediately expected. In general science it will contain the names of some distinguished men, which it is hoped will serve to give a character to the establishment, and, in some degree, counterbalance the weakness of the medical department.

MIDDLESEX HOSPITAL.

Mr. Tuson was elected, on Thursday the 2d instant, to the vacant surgeoncy in this hospital. Mr. Alex. Shaw, it is expected, will be appointed Assistant-Surgeon.

NAVAL PROMOTION.

Mr. Richard Birtwhistle, senior assistant-surgeon of His Majesty's flag-ship Caledonia, 120 guns, Mediterranean station, has been promoted by Lord Minto, First Lord of the Admiralty, to the rank of full surgeon.

ELECTION OF A MEDICAL CORONER.

Mr. Ferrier, a medical candidate for the coronership at Great Yarmouth, has been successful.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

June 2, 1836.

Lewis Jones, Peneraig (passed on the 12th May).
James Robert Cole, Odiham, Hants.
Charles Elkins, Newman-street.
Edward Dakins, St. James's, Colchester.
James Cooper, Martham, Norfolk.
John Brigham Barsham, Cambridge.
Robert Chevallier Cream, Melford, Suffolk.
James Thomas Smith, Great Hadham, Herts.

LECTURES

ON

MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

BY JON. PEREIRA, ESQ., F.L.S.

LECTURE XXXVII.

WE have now arrived at the consideration of one of the most important of our remedial agents,—namely, *Mercury*.

MERCURY, OR QUICKSILVER.

History.—*Mercury*, or *Quicksilver*, is one of the seven anciently-known metals; yet we have not the same complete account of its ancient history that we have of gold and of silver. In the Old Testament no mention is made of it, nor is it alluded to by Herodotus; so that we have no positive proof that the ancient Egyptians were acquainted with it. Lemoine, however, in his "*Treatise on Miracles*," says that the Egyptian magicians, in their attempts to imitate the miracles of Moses, employed rods and cords filled with quicksilver, which, being heated by the sun, imitated the windings of a serpent. The period when this occurrence is supposed to have taken place, is about 1500 years before Christ. You will find a similar statement in the "*Bibliothèque Orientale.*" Aristotle and Theophrastus speak of αργυρος χυτος (*argentum liquidum*); and the former of these writers mentions that Dædalus (who is supposed to have lived about 1300 years before Christ), communicated a power of motion to a wooden Venus by pouring quicksilver into it. Whether this was constructed on any principle like that of the toy called the Chinese tumblers I know not. It has also been said that Dædalus was taught this art by the priests of Memphis. Pliny and Dioscorides speak of quicksilver, and the latter describes the method of obtaining it from cinnabar.

It was first employed medicinally by the Arabian physicians, Avicenna and Rhazes; but they only ventured to use it as an external agent against vermin and cutaneous diseases. We are indebted to that renowned empiric, Paracelsus (who died A.D. 1541), for its first employment as an internal medicine.

Synonymes.—The names which have been applied to this metal are very numerous: of these, some have reference to its silvery appearance and liquid form,—as, υδραργυρος, *hydrargyrus*, and *hydrargyrum*, which are derived from υδωρ, *water*, and αργυρος, *silver*; and *argentum vivum*, *aqua argentea*, *aqua metallorum*, and the English word *quicksilver*, all of which have reference to its mobility or liquidity, and its similarity in colour to silver. It has been called *mercury*, after the messenger of the Gods, on account of its volatility. There are various other synonymes for this metal, which I pretend not to understand, such as *azoph*, and the Moorish words *zaiber* or *zabach*.

Native state.—Mercury is found in the inorganic kingdom only, and is to be regarded as a comparatively rare substance. Its ores may be arranged under three heads: 1st, *metallic quicksilver*, found either alone, (*native* or *virgin mercury*) in the form of globules, in the cavities of the other ores of this metal, or combined with silver, (*native amalgam*): 2ndly, *sulphuret of quicksilver*, called also *native cinnabar* or *vermilion*, the most important one, since from this, the metal of commerce is chiefly obtained; the principal mines for it are those of Idria in Carniola, and Almaden in Spain: 3dly, the *protochloride*, called *mercurial horn ore*, or *corneous mercury*. I ought also to add that traces of quicksilver have been met with in common salt,

during its distillation with sulphuric acid, by Rouelle, Proust, Westrumb, and Wurzer.

Extraction.—The usual method of extracting quicksilver from its ore, is to mix the native sulphuret with caustic lime, and distil in iron retorts. In this process the lime abstracts the sulphur, and the disengaged metal distils over. It is brought to this country in iron bottles, (holding from 60lbs. to 1 cwt.) the mouths of which are closed by iron screws, and also in goats' skins, two or three times double.

Properties.—At common temperatures it is an odourless tasteless liquid metal, having a whitish colour like silver or tin, and a specific gravity of 13·5. When cooled down to 38·66° F., it freezes and crystallizes in regular octahedrons. In this state it is ductile, malleable, and tenacious. Mr. Faraday has shewn that at common temperatures, and even when the air is present, mercury is always surrounded by a mercurial atmosphere; and according to Stromeyer, at from 140° to 160°, mercury mixed with water, is volatilized in considerable quantities. At 656° F. it boils, and produces an invisible elastic vapour, whose specific gravity is 6·976.

Chemists are not agreed on the atomic weight of this metal: at one time 200 was generally adopted; but several reasons led to the belief that this number was too high by one-half, and Dr. Thomson has accordingly adopted 100, and Berzelius 101·43. Dr. Turner, however, has inferred from some late analyses that it should be 202, a number which he, therefore, uses in his work. This discordance is most unfortunate, and might be adduced by the College of Physicians as a strong argument against using modern chemical names in the Pharmacopœia, since it must involve the adoption of one opinion to the exclusion of the other. For if the opinion of Thomson and Berzelius be adopted, corrosive sublimate should be termed *chloride of mercury,*—a name which, according to Turner's views, ought to be applied to calomel.

Characteristics.—Mercury, in the metallic state, is distinguished by its liquidity at common temperatures, and by its volatility. When invisible to the naked eye, and in a finely divided state, it may be readily detected by the white stain (called by workmen *quickening*) communicated to gold and silver. Thus in blue pill, blue ointment, and *hydrargyrum cum cretâ*, metallic mercury is readily distinguished by rubbing a portion of them on a shilling or sovereign. Mercurial vapour also may be detected by exposing gold or silver to its influence. If mercury be in combination with other metals, and the tests now mentioned be not applicable, we may dissolve the suspected substance in nitric acid, and proceed as I shall presently direct, in speaking of the mercurial preparations.

Impurities.—Mercury may be mechanically or chemically impure. The mechanical impurities (adhering dirt and dust) may be removed either by straining through flannel, or by filtering through a small hole in the apex of an inverted cone of paper. Chemical impurities, such as lead, tin, zinc, and bismuth, give to mercury the property of rapidly tarnishing or oxidizing in the air. To separate these, the metal, mixed with iron filings, is to be distilled in a coated earthen retort, to the neck of which a curved tube is adapted, which dips under water contained in a basin as the receiver. In the Pharmacopœia the mercury is ordered to be purified by distilling in an iron retort; but an earthen one is more convenient. In this way is procured the *hydrargyrum purificatum* of the Pharmacopœia.

Physiological effects.—We may examine the physiological effects of metallic mercury under two heads,—the effects of liquid mercury, and the effects of mercurial vapour.

(*a.*) *Effects of liquid mercury.*—From the experiments of Moulin, Haighton, Viborg, and Gaspard, it appears that when *injected into the veins*, mercury collects in the small vessels of the neighbouring organs, and acts as a mechanical irritant. Thus if thrown into the jugular vein, peripneumonia is excited; and, on examination after death, little abscesses and tubercles have been found in the lungs, in each of which was a globule of quicksilver as the nucleus.

Some difference of opinion exists as to the *effects of liquid mercury when swallowed*; one party asserting that it is poisonous, another that it is innocuous. The truth I believe to be this: so long as it retains the metallic state it is inert; but it sometimes combines with oxygen in the alimentary canal, and in this way acquires activity. Avicenna, Fallopius, and Brasavolus, declared it harmless; Sue states that a patient took for a long time two pounds daily without injury; and I could refer to the experience of many others who have seen it employed in obstructions of the bowels, without proving noxious; but the fact is so generally known and admitted, as to require no further notice. In some instances, however, it has acted powerfully, more especially where it has been retained in the bowels for a considerable time; no doubt from becoming oxidized. Thus Zwinger states that four ounces brought on profuse salivation four days after swallowing it. Laborde also tells us, that a man who retained about seven ounces in his body for fourteen days, was attacked with profuse salivation, ulcera-

tion of the mouth, and paralysis of the extremities; and other cases of a similar kind might be quoted.

Applied externally, liquid mercury has sometimes produced bad effects. Dr. Scheel has related a fatal case, attended with salivation, brought on from wearing at the breast a leathern bag, containing a few drachms of liquid mercury, as a prophylactic for itch and vermin.

(*b.*) *Effects of mercurial vapours.*—The injurious effects of mercurial vapours, when inhaled or otherwise applied to the body, have been long known. They are observed in water gilders, looking-glass silverers, barometer makers, workmen employed in quicksilver mines, and in others exposed to mercurial emanations. In most instances an affection of the nervous system is brought on, and which is indicated by the *shaking palsy* (or *tremblement mercuriel*), vertigo, loss of memory, and other cerebral disorders, which frequently terminate fatally. The first symptom of shaking palsy is unsteadiness of the arm, succeeded by a kind of quivering of the muscles, which increases until the movements become of a convulsive character. In all the cases (about five or six in number) which have fallen under my notice, the shaking ceased during sleep. I have not seen the least benefit obtained by remedial means, although various modes of treatment were tried. This is in opposition to Dr. Christison, who says the tremors "are cured easily though slowly." If the individual continue his business, other more dangerous symptoms come on, such as delirium or epilepsy; and ultimately death is produced.

In some instances salivation, ulceration of the mouth, and hæmoptysis, are produced by the vapour of mercury. The following remarkable case is an instance in point. In 1810 the Triumph man of-war, and Phipps schooner, received on board several tons of quicksilver, saved from the wreck of a vessel near Cadiz. In consequence of the rotting of the bags the mercury escaped, and the whole of the crews became more or less affected. In the space of three weeks 200 men were salivated, two died, and all the animals, cats, dogs, sheep, goats, fowls, a canary bird,—nay, even the rats, mice, and cock-roaches, were destroyed.

As metallic mercury in the liquid state is not active, it has been thought that mercurial vapour must also be inactive. Thus Dr. Christison thinks that the activity of the emanations arises from the oxidation of the metal before it is inhaled. I believe, however, with Buchner, Orfila, and others, that metallic mercury, in the finely divided state in which it must exist as vapour, is itself poisonous.

Uses of liquid mercury.—In the *first* place, liquid mercury has been used as a *chemical* agent, to dissolve silver coin which may have been accidentally swallowed; *secondly*, as a *mechanical* agent, it has been used to remove obstructions of the bowels; for example, intus-susception, or intestinal invagination. But neither theory nor experience seem favourable to its use; for in the greater number of cases the intus-susception is progressive—that is, the superior portion of the gut is insinuated into the lower portion, and, therefore, the pressure of the metal on the sides of the intestine cannot give relief; and even in cases of retrograde intus-susception—that is, where the lower portion of the bowels passes into the upper, mercury, instead of pressing the intus-suscepted portion back, might push it farther on, by getting into the angle of reflection between the containing and inverted gut. *Lastly*, water, which had been boiled with mercury (*aqua mercurialis cocta*), was at one time used as an anthelmintic: but if the metal be pure, the water takes up no appreciable quantity of it. Moreover, it would appear that mercury has no particular anthelmintic powers; for persons who were salivated have not been freed from their worms, and Scopoli very frequently found ascarides in the workers of the quicksilver mines of India.

Administration.—When taken internally it has been administered in various doses, from an ounce to a pound, or even more than this.

Mercurial Preparations.

Chemical properties.—When treated with potash or soda, globules of metallic mercury are obtained, which may be recognized by their liquidity at common temperatures, and by rubbing them on a piece of silver or gold. Solutions of the mercurial salts placed for some time in contact with a piece of bright copper, and afterwards rubbed off with paper, leave a silvery stain behind, which disappears when heated to redness. Those compounds which are of themselves insoluble in water, may be dissolved by digesting them with nitric acid; and the copper test may then be applied. In this way the mercury contained in calomel, vermilion, subsulphate and iodide of mercury, may be readily recognized. Sulphuretted hydrogen produces, with solutions containing mercury, a black precipitate.

Physiological effects. — Probably all the preparations of mercury are more or less noxious: the only doubtful exception to this statement exists in the case of the sulphurets; both of which Orfila asserts to be inactive.

(*a.*) *Local effects of mercurials.*—I believe that all mercurials act as local irritants,

but with different degrees of power: corrosive sublimate being among the most, and the protoxide among the least, active preparations. Mr. Annesley, however, seems to think that calomel is the reverse of an irritant; in other words, that it diminishes the vascularity of the gastro-intestinal membrane.

(*b.*) *Remote effects of mercurials.*—These vary in degree (not in nature) according to the kind of preparation used—the dose, the mode of application, the frequency of repetition, and so forth. I propose to examine these effects under three heads, or degrees of operation.

1. In very *small* and *repeated doses*, the first obvious operation of mercurials is an increase in the quantity of the secreted fluids. This is particularly observed in the digestive organs; the quantity of intestinal mucus, of bile, of saliva, of mucus of the mouth, and probably of pancreatic liquid, being increased; and we, therefore, find that the alvine discharges become more liquid, and contain a larger proportion of bile. The effect is not confined to these parts; for the pulmonary, urino-genital, and conjunctival membranes, become moister, the urine is increased in quantity, the catamenial discharge is sometimes brought on, the skin becomes damper and at the same time warmer. The absorbent or lymphatic system seems also to be stimulated to increased activity; for we frequently observe that accumulations of fluids in the shut sacs (as the pleura, the peritoneum, the arachnoid, and synovial membranes) diminish in quantity, become less fluid, and in some cases rapidly disappear. At the same time, also, glandular swellings and indurations of various kinds are dispersed. These are the cases in which the mercurials are called *alteratives*—that is, they indirectly induce healthy action in a very gradual manner; how, I know not; it may be, as some suspect, by their powerful influence over the lymphatic system, but the influence which several of our most important medicines (such as arsenic, cinchona, and mercury), exercise over diseases, is quite incomprehensible.

Slow or chronic poisoning. — If the use of mercurials, in these small doses, be continued for some time, the whole system becomes morbidly affected, constituting what might be termed *slow poisoning*; but the particular form of disease which takes place is liable to some variation, depending partly on the quantity of mercury introduced into the system in a given time. In some cases there is a cachectic condition produced, marked by disorder of the digestive organs, loss of appetite, wasting, incapability of much exertion, with increased secretion from all the organs, especially from the salivary glands. This state constitutes what has been called the *mercurial cachexia*, or *dyscrasia*. In other instances the nervous system becomes affected, and the *shaking palsy* induced. Sometimes *salivation* is the leading symptom; but of this I shall speak separately.

2. I proceed now to treat of the effects of mercurials taken in somewhat *larger doses*, as when we employ them as *sialogogues*. To a certain extent, the symptoms are those already mentioned; thus the action of the secreting and exhaling organs is usually increased, the cutaneous exhalation is augmented, the urine is in greater quantity, and the bowels are frequently relaxed. Of all the secretions, none are so uniformly and remarkably increased as those of the mucous follicles of the mouth and the salivary glands; and the increased secretion of these parts is accompanied with more or less inflammation, the whole constituting what is termed *salivation*, or *ptyalism*. The first symptoms of this affection are slight tenderness and tumefaction of the gums, which acquire a pale rose colour, except at the edges surrounding the teeth, where they are deep red. Gradually the mouth becomes exceedingly sore, and the tongue much swollen; a coppery taste is perceived, and the breath acquires a remarkable fœtidity. The salivary glands soon become tender and swollen; the saliva and mucus of the mouth flow abundantly, sometimes to the extent of several pints in the twenty-four hours. During this state, the fat is rapidly absorbed, and the patient becomes exceedingly emaciated. The blood when drawn from a vein puts on the same appearance as it does in inflammatory diseases. If the use of mercury be further persevered in, the mouth becomes ulcerated, the tumefaction of the gums increases, the salivary glands and tongue swell sometimes to such an extent that the latter hangs out of the mouth, incapacitating the patient from either eating or speaking. In some cases the gums slough, and the teeth loosen and drop out: and occasionally necrosis of the alveolar process takes place. During this time, the system becomes extremely debilitated and emaciated, and, if no intermission be given to the use of mercury, involuntary actions of the muscular system come on, and the patient ultimately dies of exhaustion.

Of the quantity and quality of saliva and buccal mucus secreted under the influence of mercury.—The *quantity* of saliva and buccal mucus discharged by patients under the influence of mercury, varies according to the quantity of the remedy employed, and the susceptibility of the patient. Formerly, salivation was carried to a much greater extent than it is at the pre-

sent day; and in the early part of the last century, from two to three quarts of saliva, in a day or night, was "accounted a good and sufficient discharge:" so, at least, we are told by Dr. Turner, a writer of that period.

And now with regard to the *quality* of the saliva discharged during ptyalism. Dr. T. Thomson analysed some, and gives the following as its contents:—

Coagulated albumen	0·257
Mucus (with a little albumen)	0·367
Chloride of sodium	0·090
Water	99·286
	100·000

The nitrates of lead and mercury produced copious precipitates with it; but the ferrocyanuret of potassium and infusion of galls had no effect. Its specific gravity was 1·0038; it was an opal fluid, and, by standing, deposited flakes of coagulated albumen.

According to Dr. Bostock, the saliva discharged under the influence of mercury, differs from that of health, in being less viscid, and in containing a substance analogous to uncoagulated albumen, such as it exists in the serum of the blood, so that it would seem the mercurial action alters the secretion of the salivary glands and makes it more analogous to the exhaled fluids of the serous membranes.

Fourcroy, Thomson, Bostock, Devergie, and several others, have not been able to detect the least trace of mercury in the saliva. Others, however, assert they have been more successful.

Eczema mercuriale.—Occasionally, during the progress of a mercurial course, there appears a vesicular eruption, which has had various names—namely, *hydragyria*, *mercurial lepra*, *mercurial erythema*, and *eczema mercuriale*. It occurs very rarely, and I have only seen two instances of it; in both of which it was very slight, and was seated on the side of the body. But out of forty-three cases which Dr. Alley saw in ten years, eight terminated fatally. The disease consists of innumerable, minute, and pellucid vesicles, which have been mistaken for papulæ: these give the appearance of a diffused redness to the skin, and a sensation of roughness to the touch. Sometimes it is preceded and attended by febrile disorder. It usually terminates by desquamation. In some cases a copious discharge takes place, and along with the epidermis the hair and nails fall off. There is usually some affection of the respiratory organs, indicated by dry cough and tightness of the præcordia.

Pseudo-syphilis.—Here also is the proper place for noticing another supposed effect of mercury—I mean the production of a disease similar to syphilis, and which has been termed *pseudo-syphilis*, the *mercurial disease*, or *hydrargyrosis*. It has long been observed that mercury is not always capable of removing the symptoms of syphilis; nay, in some cases it has appeared to make them worse. Now as they sometimes disappeared when we left off the use of the mercury, it was supposed that they were in fact the effects of the remedy, and not of the disease, and thus we read of buboes, chancres, and ulcerated throats, iritis, affections of the bones, of the periosteum, of the tendons, and of cartileges, produced by mercury, but I believe without any foundation. We never see them produced except when mercury has been employed for the cure of venereal affections, while on the other hand, all these symptoms may occur when this metal has not been used. In tropical climates, where it is given in immense quantities, these effects are never observed; but on this point I cannot do better than refer you to Dr. Musgrave's paper in the 28th volume of the *Edinburgh Medical and Surgical Journal*, and to Dr. Currie's *Examination of the Prejudice commonly entertained against Mercury.*

Non-mercurial salivation.—It is a point of some practical importance to know, that many causes besides the use of mercurials may bring on salivation. I have already noticed several other substances which occasionally have this effect; for example, hydrocyanic and arsenious acids, and tartar emetic. But in some instances salivation comes on spontaneously, that is, it occurs without any obvious cause. I have seen about a dozen cases of this kind, most of them females, in none of whom could I find the least reason to suspect they had taken a particle of mercury, for at least many months before they were under my care; the symptoms were precisely those caused by mercury, not even omitting the odour of the breath. The most remarkable case occurred very recently; here is a slight sketch of it.

Remarkable case of spontaneous salivation.—A man affected with rheumatism, sent to a surgeon for advice, who, without seeing him, prescribed some pills, one of which was to be taken thrice daily. At the end of the week, his rheumatism not being relieved, he sent his wife again to the surgeon, who ordered the pills to be repeated. Another week elapsed, when the patient requested Mr. H. W. Coward, surgeon of the New North Road, Hoxton, to see him, to whom I am indebted for part of the particulars of this case. Mr. Coward found his patient with the following symptoms: fever, great prostration of

strength, sore throat, rheumatic pains in the wrists, profuse ptyalism, more than a pint of saliva being discharged per hour, with the breath having the "mercurial" odour; and on the inner surface of the right cheek a foul ulcer. He ascribed his present condition to the pills, as he had no sore mouth until after taking them. On cutting one of the pills, it was observed to have a light-brown colour, and the odour of opium: hence it was supposed they were composed of calomel and opium. Purgatives, tonics, and gargles of the chloride of soda, were used without avail, and after some days, Mr. Coward requested me to see the patient. I found him in the following condition: right side of the face swollen and slightly red, gums swollen, red, and ulcerated, breath horribly offensive, its odour not distinguishable from that called mercurial; on the inner side of the cheek near the orifice of the parotid duct, there was a slough about the size of a sixpenny piece; salivation most profuse; in fact the saliva flowed in a continued stream from his mouth; over the body were observed a few petechiæ. Coupling this man's condition with what I may call the "moral" circumstances of the case, I concluded that these symptoms arose from the use of mercury. Notwithstanding the means employed, the man became worse, the sloughing gradually increased until the whole of the right cheek became involved, and in about a week from my first visiting him he died.

A day or two before his death, I called upon the surgeon who had prescribed the pills, to tell him of the dangerous condition of the patient, arising, as I then thought, from the use of mercury. He assured me that the pills contained the Dover's powder only, and not an atom of any mercurial preparation. These pills he kept ready prepared, as he was in the habit of prescribing them frequently. To prove the correctness of his statement, he called his assistant, who made and dispensed the pills, and shewed me his day-book, in which was contained this patient's prescription. Furthermore, on comparing the pills which were already prepared with those taken by the patient, they were found to be identical.

Mercurial erethysm. — Under the term "*mercurial erethysm*," Dr. Christison includes all the secondary and chronic effects of mercury—such as salivation, shaking palsy, &c. But I use this term in the sense it was employed by Mr. Pearson—namely, to indicate a particular morbid condition of the system brought on by mercury, and which frequently terminates fatally. It is characterized by great depression of strength, a sense of anxiety about the præcordia, frequent sighing, trembling, a small quick pulse, sometimes vomiting, a pale contracted countenance, and a sense of coldness; but the tongue is seldom furred, nor are the vital or natural functions much disordered. When these symptoms are present, a sudden and violent exertion of the animal power will occasionally prove fatal.

Discoloration of the skin. — Harrold, in Meckel's *Archiv*, mentions the case of a man who was submitted to a mercurial course, after having used sulphur internally, and who, in consequence, became black. Dr. Rigby has also related an analogous case, in the London Medical Repository.

A female affected with itch and syphilis was admitted into one of the pauper establishments of Norwich. "Sulphur ointment was used in the first instance for the cure of the cutaneous disease, and soon after, while the fœtor of the skin sufficiently evinced the continued sulphurous impregnation, she began the mercurial friction. When the mouth became affected, the skin began to assume a dirty blue colour, and, by degrees, the mercurial friction going on it became quite black, the patient exhibiting the appearance of an Æthiopian." It would seem, therefore, that the sulphur and the mercury were each thrown out of the system by the cutaneous organ, and immediately they were out of the sphere of the vital powers, they entered into union and formed the black sulphuret of mercury, which was deposited on the surface of the skin, in a pulverulent form, for it soiled the linen, and a dirty black powder was separable from both the skin and the linen; and, soon after the mercurial friction was discontinued, the stain disappeared.

3. *Acute poisoning.*—When *large doses* of some of the soluble salts of mercury have been swallowed, *gastro-enteritis* is observed. The patient complains of an acrid styptic taste in the mouth, and of a feeling of burning and tightness in the throat; the face is usually flushed and sometimes swelled, violent vomiting and purging (frequently of bloody matters) soon come on, the vomiting being increased by every thing taken into the stomach; oftentimes there is irritation of the urinary passages, and sometimes even suppression of urine: the pulse is small, frequent, and contracted—the respiration difficult—the extremities cold. In some cases *salivation* is produced; this seldom comes on during the first 24 hours,—and in those instances, in which it does occur, is seldom delayed beyond the fourth day. Towards the termination of the case, some indications

of *disorder of the cerebro-spinal system* come on,—such as slight drowsiness, or stupor, or even coma,—tremors and twitchings of the muscles, and sometimes even violent convulsions—in some cases paraplegia. These symptoms terminate in death. Post-mortem examination discovers inflammation, and its consequences, of the gastro-intestinal membrane.

Theory of the operation of mercurials on the system.—I propose to examine, under this head, several points connected with the operation of mercurials, which are of a debatable or disputable kind.

(*a.*) In the first place, *does mercury become absorbed?* That mercury does enter the blood, and is afterwards either deposited in some of the solids of the body, or thrown out of the system by the excretories, is proved, I think, beyond the shadow of doubt. The proofs are three-fold.

In the *first* place, mercury has been detected in the blood by Zeller, by Buchner, by Colson, and by Schubarth. Many persons, however, have failed to discover it in this fluid; and it would appear, therefore, either that this metal is not invariably present, or that it is in some peculiar state or mode of combination, so as not to be recognizable by the usual means of analysis: for the failure cannot always, I think, be referred to defective manipulation, as some very dexterous chemists have failed in detecting it.

Secondly, mercury has been found in the perspiration, in the saliva, in the gastro-intestinal secretion, in the bile, and in the urine. M. Colson, in the 12th volume of the *Archives générales*, has given a list of the persons who have in this way detected mercury—and to his paper I must refer those interested in this inquiry. Now, since the secreted and exhaled fluids are formed from the blood, the detection of mercury in them is a sufficient proof of its previous existence in the latter.

Thirdly, this metal has been found in the bones, brain, synovial capsules, pleura, humours of the eye, cellular tissue of the perineum, in the lungs, &c.; and here I must again refer you to M. Colson's paper for a list of the authorities on this point,—as well as to Wibmer's work, "*Die Wirkung der Arzneimittel und Gifte.*"

(*b.*) The second question to be examined is this:—*Are the constitutional effects of mercury the consequences of its absorption?* I believe we ought to answer this in the affirmative, and on three grounds:—

In the *first* place, mercurials affect the general system to whatever part of the body they may be applied, whether to the mucous membranes, the cutaneous system, (Dr. Wilson Philip has seen a mercurial plaster affect the gums), the cellular tissue, or injected into the veins. *Secondly*, the action of mercurials on the system is assisted by the use of bloodletting and emetics, agents which promote absorption. *Thirdly*, when mercurials are administered by the stomach, and excite purging, they rarely affect the general system, apparently in consequence of the function of absorption being suspended.

The operation of mercurials, therefore, seems to be best explained by supposing that the metal gets into the blood, and thus is brought in contact with all the tissues of the body, on some of which it operates more powerfully than on others, in consequence of some peculiar modifications in the state of their vital properties.

(*c.*) *On what parts does mercury seem to act specifically?*—In the first place it is obvious that it operates in a remarkable manner on the *secreting* and *exhaling* organs (particularly on the mucous follicles of the mouth and the salivary glands). The liver also, in common with other secreting organs, feels the stimulus thus communicated to it; and some writers imagine, it is specifically influenced in a more distinct manner than other glands. Thus Dr. Wilson Philip says, "mercury has a specific operation on the liver, a power not merely of exciting its functions, but of correcting the various derangements of that function in a way which it does not possess with respect to any other organ, and which no other medicine possesses with respect to the liver." I confess I am not acquainted with any facts warranting this assertion; for I have seen mercury as efficacious in hemiplegia, as can have been observed in affections of the liver. The purgative effects of mercury arise partly from the increased secretion of bile, and partly from the stimulus given to the mucous lining of the alimentary tube, more particularly to its follicular apparatus.

The *nervous system* appears also to be specifically affected by mercurials. This is to be inferred partly from the effects produced in those subjected to the vapours of this metal, such as the shaking palsy, &c. and partly from the effects of the soluble salts, when given in enormous doses.

The *heart* and *lungs* are, in some cases, remarkably affected. This was particularly observed by Sir Benjamin Brodie, in his experiments on animals with corrosive sublimate; as also by Smith, Orfila, and Gaspard.

The affection of the *urinary organs* in poisoning by corrosive sublimate is also not to be forgotten.

(*d.*) The next question we have to discuss is one which necessarily involves much hypothesis; it is—*What kind of influence does mercury exercise over the system?*—The answer to it is so closely related to that of another question; namely, *how do mercurials affect diseases, particularly syphilis?*—that I shall examine the two questions together.

The action of mercurials on the system, and their influence over diseases, have been explained at different periods in different ways, according to the then prevailing theory: and thus, at one time, their influence was attributed to their mechanical, at another to their chemical properties; according as the prevailing hypothesis of the day was founded on mechanical or chemical notions. Not finding these ideas satisfactory, others have attempted to explain the action of mercury (as well as of other remedies) independent of mechanical or chemical details. It would be a waste of time to enter into particulars respecting these theories, except, perhaps, so far as to point out how they were applied, so as to explain the influence of mercury over diseases, more especially syphilis. For convenience, I shall arrange these theories under two heads,—according as they are founded on mechanical or chemical considerations, or are independent of them.

1. *Mechanico-chemical hypotheses.*—(*a.*) Astruc and Barry fancied that mercury acted by its weight, its divisibility, and its mobility; and thus getting into blood separated its globules, rendered it more fluid and more fit for secretion, made the lymph thinner, and overcame any existing obstructions. (*b.*) Others have fancied that certain diseases, as syphilis, depended on poisons contained in the blood, and that mercurials caused their evacuation by the different secretions, as by salivation, by purging, by perspiration, or by expectoration. This was the opinion of Cullen, of Murray, and of Brefeld. But a very simple answer may be given to this hypothesis,—namely, that the beneficial influence which mercurials exercise over diseases is not proportionate to their evacuant effects. (*c.*) The action of mercurials on the secretions was explained by Dr. Cullen on chemical grounds: mercury, says he, has a particular disposition to unite with ammoniacal salts, with which it passes off by the various excretions; and as the saliva was supposed to contain more of these salts than other secretions, he thus accounted for the larger quantity of mercury which passed off by these glands, and the consequent salivation. But the whole hypothesis falls to the ground, when it is known that mercury has no "particular disposition" to unite with the ammoniacal salts, and that even if it had, other secretions are as abundantly supplied with these salts as the saliva. Dr. John Murray substituted another hypothesis, but equally objectionable: mercury, says he, cannot pass off by the urine because of the phosphoric acid contained in this fluid, and which would form, with the mercury, an insoluble compound. It must, therefore, be thrown out of the system by other secretions, particularly by the saliva, which facilitates this transmission by the affinity which the muriatic acid, the soda, and the ammonia of the secretion, have for the oxide of mercury, and by which a compound soluble in water is formed. The answer to this hypothesis is, that mercury *is* thrown out of the system by the urine, and probably in larger quantity than by the saliva; secondly, the saliva also contains phosphatic salts, according to Tiedemann and Gmelin. (*d.*) Some have explained the efficacy of mercury in syphilis, by supposing that it acted chemically on the syphilitic poison, as acids and alkalies act on each other. I may refer to Mitié, Pressavin, and Swediaur, as supporters of this notion. But if it were correct, the larger the quantity of mercury employed, the more effectually subdued would be the venereal disease which we know not to be the case. (*e.*) The last chemical hypothesis which I shall notice, is that which supposes the efficacy of mercurials to depend on the oxygen they contain. This was originally suggested by Girtanner, and led to the use of acids and other oxygenated substances, as substitutes for mercury. Several facts might be adduced against it, but I shall only notice two,—namely, that other substances which contain as much oxygen, and give it out as readily, are not equally beneficial in syphilis; and that those mercurials which contain the least portion of oxygen, are more useful remedies than others containing a larger quantity.

2. *Dynamical, physiological, or vital hypotheses.*—(*a.*) Some term mercury a *stimulant*, and refer all its beneficial effects in diseases to its stimulating properties. But those who adopt this hypothesis are not agreed as to whether particular parts are stimulated or the whole system, and if particular parts, what these are; since Hecker fixes on the lymphatic system, Schöne on the arterial capillary system, Reil on the nerves. The simple answer to all of them is, that other stimulants are not capable of producing the same effects on the constitution as mercury; nay, are frequently hurtful in the very same cases that mercury is beneficial. (*b.*) The op-

posite opinion—that mercury is a *weakening* or *sedative* agent—has also been maintained by some. Thus Horn says that it is a direct weakening agent, and at the same time, by the evacuations, it produces an indirect one. Hence those who adopt this hypothesis, must assume that the diseases in which mercury is beneficial are of a phlogistic or hypersthenic character; and that syphilis, therefore, is of this nature: an explanation not at all satisfactory, nor consistent with facts. Of late years, the sedative operation of some of the mercurial preparations (calomel and mercurial ointment) has been assumed (particularly by our countrymen practising in the East), from the circumstance that these agents allay vomiting and diarrhœa in yellow fever, cholera, and other dangerous diseases. But even admitting that mercurials do produce these effects, this is hardly a sufficient ground for denominating them sedatives. Some think that mercurials, in small or moderate doses, are stimulants, but in excessive doses, sedatives; and that this sedative operation is common to all substances when employed in large quantities. This is the opinion of Dr. Wilson Philip. Practitioners of the East appear to ascribe the sedative effects of mercurials chiefly or wholly to two preparations—namely, calomel and mercurial ointment; and Dr. Gibson goes so far as to assert that blue pill is perfectly inadequate to any good purposes; nay, he says it is generally inert in India.

(*c*.) But mercury is not to be regarded as a mere stimulant, or a mere sedative—that is, as not affecting merely the *degree* of the actions of the system, but as also influencing their *quality;* and in this way, I presume, we are to explain its influence over diseases, especially syphilis. It is thus that Mr. Hunter accounts for its beneficial effects; for he says it produces an irritation of a different kind from that caused by the venereal disease, and that it counteracts the latter by destroying the diseased action of the living parts.

Thus, then, after this long account of the *modus operandi* of mercury, the conclusions at which we have arrived are rather of a negative character, and lie in a very small compass: it appears that this metal becoming absorbed, excites a new action in the system, differing, not merely in degree but also in quality, from other morbid actions, and from healthy; and that this capability of exciting a new action in the system, is not referrible to any known mechanical or chemical properties possessed by mercury.

AN ACCOUNT

OF

SOME CASES OF TRANSPOSITION OBSERVED IN THE HUMAN BODY*.

By Dr. Watson.

The following unusual disposition of the viscera was unexpectedly discovered in examining the body of John Reid, who had been a patient of mine in the Middlesex Hospital, and who died there in October last. He was 48 years old.

The mediastinum was observed to slope to the right from above downwards. The heart and pericardium lay on the right side of the sternum, and pointed, in a slanting direction, towards the right. The right lung was divided into two lobes only; the left into three. The aortic chambers of the heart were situated posteriorly on its right side; the pulmonic anteriorly on its left. The arch of the aorta passed obliquely across from left to right. The left carotid and subclavian arteries sprang from the aorta by a common trunk; the right carotid and subclavian were given off separately. The venæ cavæ opened into their proper auricle on the left side of the spine.

In the abdomen the aorta descended, between the crura of the diaphragm, on the right side of the inferior cava. The apertures in the diaphragm, and the bearings of its several parts, presented a corresponding interchange of relative position. The liver occupied the left hypochondrium, the gall-bladder lying in the under part of its left and thickest lobe. The stomach had its larger extremity and cardiac orifice in the right hypochondrium; the pylorus being in the left: and on the right of the stomach was the spleen. The cæcum was found in the left flank; and the colon mounted on the left side, passed transversely across from left to right, and descended on the right side to terminate, by the sigmoid flexure, in the rectum. The left kidney was placed about an inch and half lower than the right. Before the body was opened, it had been noticed, that the right testicle hung lower than the left.

The whole variation from the ordi-

* Read at the evening meeting of the College of Physicians, May, 30, 1836.

nary arrangement, *apparent to the eye*, may be summarily stated thus:—Throughout the body, all the organs which, though occurring in pairs, differ, each from its fellow, in some notable particulars of figure or position—as the lungs and kidneys—were mutually transplaced, and lay on the opposite side of the body to that which may be called their normal side; and all the single and unsymmetrical organs,—as the heart, liver, and intestines,—were not only found on the contrary side to that on which they commonly lie, but had, also, (like the former organs) their own correlative parts and aspects similarly reversed in position from right to left, and from left to right.

It would, however, be inexact to speak of the change as being limited to the parts hitherto mentioned. Doubtless, it was complete and universal. But, of those organs which are double, and correspond in all points to each other, as the eyes, the ears, the limbs; or which, being single, are composed of symmetrical halves, as the nose, the brain, the spinal chord; we distinguish the right from the left organ, or the right from the left moiety, only by the relative positions of its constituent parts: and these positions being themselves also laterally reversed, the translocation of such organs or halves is no longer obvious to the sight, although analogy leaves the fact of its existence scarcely questionable.

To those who are unacquainted with anatomical details, but yet are aware that "whilst the cavities of the body are so configurated as *externally* to exhibit the most exact correspondency of the opposite sides, the contents of these cavities have no such correspondency*," the nature of the variation displayed in this particular instance may be made clearer by stating, that the viscera within the chest and belly, when exposed to view, presented exactly the appearance which the same viscera, under the usual conformation, would present, if seen reflected from a plane mirror: and, conversely, that the image of the viscera, in this abnormal case, would resemble a picture of the viscera in their normal or more common form and arrangement.

Or, as Winslow has well observed of such cases, the viscera thus unusually disposed, may be said to resemble the viscera in their ordinary disposition, as the left hand resembles the right.

The reversed heart, from the Anatomical Museum of King's College, is upon the table.

But to those who are here present this evening, I fortunately have the means of giving a better notion of this anomalous formation, than can be derived from any verbal description. After this paper was written, I accidentally learned that another case of precisely the same kind had recently occurred in London, and that a preparation of it had been made by Sir Astley Cooper. Sir Astley has done me the favour of allowing me to show you that preparation—which is no less beautiful as a work of art, than it is curious as displaying a freak of nature. He has further obliged me with some particulars of the case, which I shall take the liberty of laying before the College in his own words. It may be as well to premise, that certain points adverted to by him had already been touched upon by myself, in a subsequent part of this paper. The preserved specimen tells its own story.

Sir Astley Cooper's Case.

"Mr. Braine, surgeon, of St. James's Square, in making a *post-mortem* examination of a woman, who had been a patient of his, was surprised at observing the cæcum, with its vermiform process, placed in the left iliac fossa, upon the iliacus internus muscle, in the usual situation of the sigmoid flexure of the colon; and, upon further investigation, he observed a complete transposition of the thoracic and abdominal viscera. Mr. Braine had the kindness to send me word, that he would be glad to show me this rare occurrence; and on the following day I had the pleasure of meeting him, Mr. Bransby Cooper, Mr. French, and Mr. Balderson, at the inspection of the body.

"After a careful examination of the position of the different viscera, I requested permission to make a preparation of the parts, with which request Mr. Braine had the great kindness to comply.

"The viscera were removed with care by Mr. Balderson, and sent to my house, where, having injected them, I had them dried and preserved; and have now the pleasure of sending the pre-

* Paley's Theology, c. 11.

paration to the President and Members of the Royal College of Physicians for their inspection.

"The name of the woman was Susan Wright. She was in her 74th year. Her height was 5 feet 5½ inches. Her form was peculiarly symmetrical and perfect, and nothing had been ever discovered to lead to a suspicion of her having any unusual conformation. She had been an inhabitant of Chelsea for many years, and had been in the capacity of housekeeper in a gentleman's family; but since the year 1824 she had lived in London, and from that time to her death had been under the constant observation of several medical gentlemen, who, if there had been any thing peculiar in her conduct, manner, or physiological functions, must have discovered it.

"Her principal employment was that of being an attendant of the sick wards of the institution in which she was placed,—and in that situation she was frequently called upon to dress the wounds and ulcers of the surgical patients, in doing which she exhibited a remarkable degree of adroitness; and all who had observed her agreed, that she gave the preference to the use of the right hand.

"In her disposition she was remarkably kind and humane, ever anxious to extenuate the faults and lessen the sufferings of others, to overlook their improper conduct and excesses, to administer to their wants, and to commiserate their misfortunes.

"Her habits were generally extremely temperate, although she had been upon a few occasions observed in a state of inebriation. She had never been married, and the appearances after death shewed that she had died a maiden, as the *hymen* still remained, and there was a more than usual elongation of the perineum over the orifice of the vagina.

"Her general health had been remarkably good until two years before her death, when she had a severe attack of fever, from which, however, she gradually recovered, and returned to her usual occupations.

"She died of *diarrhœa*, on the 19th of March, 1836.

"*Post-mortem examination.* — The transposition of the thoracic and abdominal viscera was complete; the basis of the heart was placed to the left, and its apex to the right side. The left lung was divided into three lobes, and the right into two. The trachea passed down upon the left side of the neck, whilst the œsophagus was situated to the right; and the left bronchus was larger than the right.

"With regard to the abdominal viscera, the liver and gall-bladder were found upon the left, the spleen and cardiac extremity of the stomach upon the right side. The pancreatic duct, and ductus communis choledochus, terminated in the duodenum at the same point upon the left side. The cæcum, with its appendix, occupied the left iliac fossa. The left kidney was placed lower than the right, in consequence of the liver occupying the left side of the abdomen; and the right emulgent vein was longer than the left.

"The diaphragm also was completely transposed, both in its crura, and in its tendinous part. The inferior cava passed through its tendinous portion on the left side, whilst the œsophagus penetrated the muscular structure on the right.

"The blood-vessels had undergone the same transposition, the curvature of the aorta passing from the left to the right side, and sending off the arteria innominata to form the left carotid and left subclavian arteries; next, the right carotid; and lastly, the right subclavian artery;—and the aorta then descended upon the right side of the spine, both in the chest and the abdomen, to form its bifurcation on the right side of the lumbar vertebræ. The vena azygos appeared on the right side of the aorta. The vena cava inferior penetrated the tendinous opening in the diaphragm on the left side, entering what was, in this subject, the left auricle of the heart. The right spermatic vein terminated in the right renal vein, and the left in the inferior cava. The vena portæ entered the liver on the left side.

"I injected the thoracic duct from the second lumbar vertebra, and it took its course to the lower part of the neck on the right side; but the jugular and subclavian veins had been removed before I saw the subject, and, consequently, the direct termination of the thoracic duct had been destroyed.

"As the viscera were removed from

the body for the purpose of being prepared, the connexion of the nerves was in a great degree destroyed; and I cannot, therefore, speak positively as to their distribution.

"The only circumstance in which the anatomy of this woman differed from others was in the existence of two superior cavæ, one placed upon the right, and the other upon the left side, and both terminating in what was, in this subject, the left auricle. But I have occasionally seen this variety in the anatomy of men, in whom there had been no transposition of the viscera; and it occurs frequently in quadrupeds in whom the entrance into the thorax is narrow.

"The uterus and ovaria were exceedingly small, and quite of the character of these parts in a girl of from 15 to 20 years.

"Upon the whole, then, it appears that the transposition of the thoracic and abdominal viscera, when it is complete, produces no change in the functions of the individual; and that life may be protracted to the same period as under the usual formation of the body.

"I certainly should have expected that a person so constituted would have given a preference to the use of the left hand; which did not happen in this woman; but I do not think these cases are decisively conclusive upon this point, as parents are disposed to break the habit in their children of using the left arm, and may thus destroy the disposition to the preference which they otherwise would have shewn.

"This is the fourth case of transposition of viscera which I have seen. The first was published by Dr. Baillie; the second occurred in a female patient of Dr. Crawford's, in St. Thomas's Hospital, of which I have a drawing; the third was brought into the dissecting-room of St. Thomas's Hospital, and the body having been dissected by Mr. Dease, of Dublin, the preparation was given to him; the fourth is that which I have the pleasure of now sending to Dr. Watson, for the inspection of the members of the Royal College of Physicians."

This curious variety of animal structure is by no means so uncommon as many have supposed. Dr. Baillie has minutely described* one instance of it, which he met with in his dissecting-room in Great Windmill-street, and to which Sir A. Cooper refers. He had also seen a fœtus, at the full time, with the viscera transposed; and a reversed heart that had belonged to another very small fœtus, and was preserved in the Anatomical Collection of Christ Church, in Oxford. He tells us, that after having been at the pains of consulting many authors, he had found this *lusus naturæ* mentioned by Cattierius, M. Mery, and M. Daubenton only; but by none of them with sufficient particularity. Authentic instances are, however, much more numerous than this statement would lead us to expect.

A similar formation was discovered in the body of Smithers, who was executed, in 1832, for arson and its consequences; and who, for some time previously to his trial, had lain in the Middlesex Hospital, his face and hands having been severely burned in his fraudulent attempt to destroy his house in Oxford Street by fire. His body was given for dissection to the Medical School of the London University, where preparations of the transposed parts may now be seen.

In the same year, and about the same time, a man, Benjamin Stubbington by name, and 28 years old, was killed, near Winchester, by the passage of a loaded cart across his belly. In his body, which was examined in the County Hospital by Mr. Charles Mayo and others, the same abnormal collocation of the thoracic and abdominal organs was observed to exist. I have been favoured with a particular account of this case by Mr. Druitt, who was himself present at the examination. I omit the details, however, because all descriptions of such cases must be, in substance, the same.

Another example was noticed, also in the same year, in the body of an adult mulatto, who died of cholera in the General Hospital, Calcutta. It is recorded in the MEDICAL GAZETTE†, by Mr. William Hardy, who erroneously supposed it "a case without parallel in the history of congenital malformations."

It is singular that Dr. Baillie, in the

* Phil. Trans. 1788, vol. lxxviii.
† Vol. xii. p. 79.

search he instituted among authors, should have overlooked a case which is related in one of the early volumes of the Philosophical Transactions* themselves, by a Dr. Henry Sampson. It occurred in the person of a Yorkshire clergyman, who died apparently of consumption. After describing certain morbid conditions found in his body, Dr. Sampson goes on to say, "But that which most of all surprised us was the inverted order of his bowels. His liver, which was very large, lay in the left hypochondre, and his spleen in the right. The cone of his heart was on the right side, and accordingly the larger and thinner ventricle was found on the left; and the thick one, which in others is on the left side, was in him on the right. The *great artery* descended on the right side, and the *vena cava* ascended by his liver on the left. The *œsophagus* descended to the first orifice of the stomach on the right side, which made the *pylorus* and entrance of the *pancreas* be on the left, and the first flexure of the small guts to be towards the right, so that the beginning of the *colon*, with its *appendicula*, lay at the left *os ilion*, and the *flexura sigmoidæa* towards the right. Other things that necessarily followed this site, need not be mentioned."

"This person (he subjoins) was never observed in his lifetime to have any distemper or usage which might discover this inverted situation of his bowels, nor had this contra-position any evident influence upon his diseases and death. He was about thirty years of age, a married man, had several children, was of a middle stature, healthful till toward the latter end of his time: had no prominency on his left side more than the other, was not left-handed, nor had any weakness on his left side."

The instance described by M. Mery, and referred to by Dr. Baillie, is certainly not deficient in particularity. It is fully detailed by the celebrated anatomist, Winslow, in his *Remarques sur les Monstres*, published in the *Mémoires de l'Académie Royale*, for the year 1733. He cites the original narration drawn up by Maloet, and signed by Mery and others: he states, however, that a report of the same case, made in 1689, by Duhamel, at that time secretary to the Academy, was too much abridged. It was probably Duhamel's briefer account that Dr. Baillie had seen.

The subject of this case was a soldier of the Hôtel Royal des Invalides, 72 years old. It seems to have excited much curiosity among the Parisian *savans;* and it gave occasion for the following doggrel verses:—

"La nature, peu sage, et sans doute en débauche,
Plaça le foie au côté gauche;
Et de même, vice-versâ,
Le cœur à la droite plaça."

This strange medley of vile poetry and worse taste would scarcely justify its quotation, except as a sort of curiosity in literature. It is ascribed to the pen of the celebrated Leibnitz, the contemporary, and almost rival, of our mighty Newton.

Winslow informs us, that a similar deviation from the customary formation was observed in the year 1657, in the body of a commissary of the regiment of guards, in Paris. He refers also to another example met with in 1650, in an assassin, whose body, after being broken on the wheel, was dissected at Paris by Dr. Regnier and M. Bertrand, the latter an experienced anatomist. Riolanus, who was present at the examination, afterwards described the appearances in a tract, entitled *Disquisitio de transpositione partium naturalium et vitalium in corpore humano.* It is the same case that Cattierius, of Montpellier, has recorded; and Bonetus, in his *Sepulcretum*, has copied, almost exactly, the statement of Cattierius.

Bartolinus*, after citing the same case, states that Petrus Servius, a most learned physician, had assured him that he had seen a similar position of the viscera at Rome, in 1643.

It appears from the *Bulletins de la Faculté de Médecine de Paris*, that at the sitting of the 12th of December, 1816, M. Beclard submitted to the inspection of the members of the society the trunk of an aged woman, in whom a complete transposition of all the viscera of the chest and belly had been met with.

Maximilian Stoll, in his *Ratio Medendi*, says that in the year 1767, he dissected the body of a person, (whose sex he does not mention, and who died of the black jaundice,) and found a total

* Vol. ix. No. 107.

* Hist. Anat. Rar. Cent. ij. xxix.

transplacement of the viscera "tam pectoris quam abdominis."

M. Joly has related another case, that occurred in the person of a canon of Nantes.

In the sixth volume of the *Archives générales de Médecine*, an instance is given by Dr. Dubled: his narration is quoted at length by M. Bouillaud, in his recent treatise on diseases of the Heart. The subject of this case was a man 20 years of age.

Two more examples are referred to in the fifty-third volume of the *Dictionnaire des Sciences Médicales*. One of these was in a child, 9 years old, that died of anasarca, in the Hôtel-Dieu at Lyons: the details are recorded by M. Poulin. The other, related by MM. Nacquart and Piorry, occurred in a male child of six years and a half, who died of croup.

Capuron, in his *Traité de la Médecine Légale relative aux Accouchemens*, tells us that twenty years before, he had seen a case of this nature in Bichat's amphitheatre, in the body of an infant dead of some accidental malady some time after its birth. He adds, that he is acquainted with a student in pharmacy, 30 years old, living in Paris, whose heart is situated on his right side. It is to be regretted that no observation is recorded by M. Capuron as to the position of the abdominal viscera in this person.

In the *London Medical and Physical Journal* for 1826, a case is described which fell under the notice of the late Mr. Rose, at St. George's Hospital. The subject of it was a woman 40 years old. Mr. Rose had met with another instance, in a soldier of the Coldstream Guards, who died at St. Jean de Luz, in the south of France, in 1814. This case was seen by Sir James M'Grigor, and many of our military surgeons. A similar variety was observed by Mr. Bacot, in a soldier of the Grenadier Guards, whose body was examined at Chatham. Baron Larrey, in his Memoirs of Military Surgery, mentions another example.

In the same journal for 1828, a case is cited from the *Annales de la Médecine et de Physiologie* for May in that year. It was discovered in the body of a soldier who had always enjoyed good health, but was killed in a duel. It is worthy of remark, that this man seemed to have been aware of something peculiar about himself, for he often jestingly affirmed to his comrades that, whatever the faculty might pretend, he was sure his heart was on his right side.

In the *Gazette Médicale* of last year, an account is given of a man, 25 years old, who died of fever, in La Pitié, under the care of M. Bally; and the position of whose thoracic and abdominal viscera was reversed throughout. The transplacement was detected by M. Bally while his patient was yet living, and many physicians and a great number of students were attracted by curiosity to visit and examine him. An English journal makes this comment upon the case:—"The most remarkable fact referrible to it is, that the man never experienced any inconvenience from the transposition of his organs during his life. The case is, perhaps, unique."

In the month of January, 1823, the viscera of the chest and abdomen were found transposed in the body of a female, aged about 40, which had been brought to the dissecting-room of St. Bartholomew's Hospital. Mr. Stanley has had the kindness to furnish me with the notes, which he then took, of the appearances. His description of them necessarily accords, in the main, with those already given, but he mentions one circumstance which renders this case peculiarly interesting.

In a former part of this paper, I expressed my belief, that the transposition or interchange between the two sides is total and absolute. The circumstance to which I allude throws some slight shade of doubt over the correctness of that notion. Mr. Stanley found the left nervus vagus in its ordinary place, *i. e.* upon the front part of the œsophagus, while the right nerve lay behind it.

If future observation should shew this disposition of the par vagum to be invariable in such cases, it will strengthen the opinion, which I believe Mr. Stanley entertains, that the translocation belongs primarily and essentially to the machinery of the circulation; and that the other structures of the body, and the nervous system in particular, are reversed only to the extent necessary for adapting them to the altered situation of the blood-vessels. The recurrent nerve, however, was found in Mr. Stanley's case, as well as in those described by Dr. Baillie and by M. Bally, to wind, on the right side,

round the arch of the aorta, and on the left round the subclavian, or the common trunk of the carotid and subclavian arteries*.

The instances now cited, or referred to, amounting in number to twenty-nine, are quite enough to shew that this variety of configuration, though rare, is far from being unique. With greater leisure and opportunity for research, more might probably have been collected. M. Isidore Geoffroy St. Hilaire, who has applied to the phenomenon the appropriate and convenient name of *heterotaxy*, speaks of fifty or sixty well-authenticated examples of it recorded by different observers. He mentions having seen one himself, but relates no particulars of any.

Heterotaxy has hitherto been noticed much oftener in males than in females. This is perhaps a mere accident. Among the twenty-nine instances referred to in this paper, there are eight (including fœtuses) in which the sex is undetermined. Of the remaining twenty-one, sixteen occurred in men, and five only in women†.

Much curiosity has been shewn to learn whether the individuals thus constructed have been *left-handed*. There is no instance recorded, that I am aware of, in which this was known to have been the case; but there are several (those, for example, of John Reid and of Benjamin Stubbington, and those described by Dr. Sampson, Dr. Baillie, and Sir Astley Cooper), in which the fact was ascertained, upon inquiry, to have been otherwise.

This question connects itself, I presume, with two notions very commonly entertained, — namely, 1st, that the greater degree of strength and readiness, which belongs so generally to the right hand and arm, as to have given to the term *dexterity* its peculiar meaning, is a natural endowment, inherent in the human frame; and, 2dly, that this superiority of endowment is determined by some necessity or preference arising out of the unsymmetrical disposition of the internal parts of the body.

The following appear to be the principal grounds of the belief that the prevailing superiority of the right hand is an original gift of nature:—

1. The employment of the right hand in preference to the left is universal throughout all nations and countries. I believe no people or tribe of left-handed persons has ever been known to exist. The investigation of this point, in regard to the inhabitants of the South-Sea Islands, formed a part of the instructions of the French government to Perouse, previously to his last voyage of discovery, of which he never returned to relate the history. Among the isolated tribes of North America which have the most recently become known to the civilized world, no exception to the general rule has been met with. Captain Back has informed me that the wandering families of Esquimaux, whom he encountered in his several expeditions towards the North Pole, all threw their spears with the right hand, and grasped their bows with the left.

In answer to the strong presumption supplied by this fact, it has been thought no unreasonable hypothesis that the habit of using the right hand may have been derived from a common ancestor, in whom it was accidental; and that it has since been transmitted through all nations, from generation to generation, by the mere force of custom or prejudice.

2. Another reason assigned for believing the right hand to possess an original pre-eminence, is, that a similar degree of superior vigour appertains to the right side of the body generally,—that the left leg of an opera-dancer requires twice as much training and exercise as the right,—that we use the right eye in looking along a gun, or through a telescope,—incline the right ear when listening intently to faint or distant sounds, and so on.

But here again it may be argued that a more frequent and habitual exercise of the other dextral limbs and organs, and consequently a greater facility in their use, would naturally follow the greater efficiency and forwardness on all occasions of the right hand, whether that be innate or acquired.

There are many, therefore, who deny that the right limbs possess any original or natural superiority; and who maintain that the difference of power which we perceive between the two sides is altogether acquired by practice. For, they say, it is notorious that the more frequent use of the right hand is in part, and therefore probably it is entirely, the result of training and edu-

* See additional remarks, p. 402.
† Ibid, p. 403.

cation; that it has become the fashion to consider a left-handed person an awkward person; and that to be left-handed in a community of right-handed people, is in some respects a real inconvenience; that children are therefore carefully drilled, when young, into the habitual employment of the right hand for certain purposes; and that the habit thus formed, and the prejudice thus created, not only continue through life, but are diligently inculcated upon the next generation. It is even believed by some that the offspring of a right-handed generation, if left entirely to themselves, would be almost all left-handed, and *vice versâ;* inasmuch as a right-handed nurse carries her infant, for that reason, chiefly on her left arm, and therefore in a position which leaves the left arm alone of the child at liberty to move.

The advocates of the dextral side of the question would probably admit this as a sufficient explanation of the frequent necessity that arises for correcting the sinistral tendency in children.

It has been alleged that the children of left-handed persons are often left-handed; that the disposition is hereditary, and therefore must be inherent. But in such cases it is not unlikely that less than the usual care is employed to correct the peculiar tendency; and even an equal degree of care would in some measure be countervailed by the practical encouragement furnished in the habitual example of the parent.

Whether man be naturally a right-handed animal or not, seems, then, a question neither settled nor easy to be decided If I may venture to express my own opinion on the subject, it is that the dextral tendency is implanted by nature; but that it cannot be very strong, since, in spite of the aid of training, it is so often overcome by slight external influences.

Taking for granted that the faculty of right-handedness is innate, some anatomists have endeavoured to account for it by the way in which the two upper extremities are supplied with blood. The right arm, they conceive, is stronger and more vigorous, because the right carotid and subclavian arteries spring from a common trunk. It is implied in this argument, either that more blood is thus sent to the right than to the left arm, or that it is sent with greater force,—propositions, either of which it would be extremely difficult to prove. Cheselden's view of the matter seems more philosophical. He regarded the difference as a compensating contrivance, and thought that "the advantage which the left arteries gain by going off at an angle much more acute than the right, is made up to the right by their going off together in one branch *." The cause alleged, therefore, namely, the different origin of the arteries, scarcely comes within the notion of a *vera causa*. Many other hypotheses, quite as plausible, and quite as uncertain, might readily be invented. It might, for example, be imagined that as the heart, situated on the left side, is a highly vital organ, this dextral tendency, which throws the right side of the body forwards in defence upon the approach of danger, provides for the better protection of a part so important.

But however this may be, it is plain that observations made upon these examples of heterotaxy are not calculated to determine the question as to the effect of the different mode in which the blood is transmitted from the aorta to the two arms. If, indeed, the individuals of the transposed variety were in all cases left-handed, this would afford a valid presumption that the preference of one hand above the other was not only natural, but some how connected with the relative position of the unsymmetrical parts; but it would not even tend to prove that the manner in which the carotid and subclavian arteries leave the aorta has any thing to do with the matter.

Very little light, however, can be expected to be thrown, by such cases, upon this question of the pre-eminence of the right hand; inasmuch as the tendency, if it be a natural one, is so easily set aside by early care and teaching. I have adverted to the question chiefly to show that, as far as it relates to the way in which the arteries arise, it is perfectly idle and inconsequential.

Neither do the terms *malformation* and *monstrosity* appear to be properly applicable to cases of this nature. Malformation implies a structure that is faulty, as well as uncommon; some defect, or excess, which often renders the organ so malformed less fit for its peculiar function. We do not consider those

* Paley's Theology, c. 11.

individuals to have been malformed, in whom we find several spleens, or a single horse-shoe kidney. In these cases of heterotaxy there is nothing constructed amiss, nothing wanting, nothing superabundant; therefore, nothing monstrous. Every part and organ is as perfect as in the ordinary fashion; and, *à priori*, we can perceive no reason why the viscera should be disposed in the one way rather than in the other. The heterotaxy constitutes a mere *variety;* and as such is strictly analogous to a like phenomenon not unfrequent among certain mollusca. It is well known, that, in most of the spiral shells, the whorls are uniformly twisted from left to right, and that the mouth of the shell, when placed opposite the spectator, lies on the right side of its axis. There are, indeed, some species, and even a few entire genera, which are invariably *sinistral*, or contorted in the opposite direction. But, what alone is to the purpose, there are species in which the reversed direction of the whorls (then called, by conchologists, *heterostrophe*) happens only occasionally, and, as it would seem, by accident. Exceptions of this sort occur in various species of Helix—as in the Helix pomatia, and the Helix hortensis, or garden snail; in the common whelk also, the Buccinum undatum. The whole shape of the mollusca inhabiting these shells presents a corresponding alteration. Now, in creatures of this kind, the variation is displayed externally, and is therefore always noticed; and it seems not an improbable conjecture that a similar anomaly may frequently obtain, though it is less frequently detected, among those orders of living beings in which the irregular parts are concealed within a uniform and symmetrical outside. I know of no authenticated instance of this departure from the standard arrangement among quadrupeds; but I have been told, by a butcher, that it sometimes occurs in sheep *.

By regarding the anomaly in the light of a mere variety, we perceive the unreasonableness of the wonder which has sometimes been expressed, that the subjects of the heterotaxy experience no inconvenience from their peculiar formation, nor enjoy a shorter span of life than others. It would be difficult to conceive a reason why they should. We are not sensible of any advantage, or comfort, from having the heart on the sinister and the liver on the dexter side; and therefore we cannot expect that any embarrassment or uneasiness should arise when that arrangement happens to be reversed.

Still it is not a little remarkable that the altered relation of the viscera should have been so seldom discovered during the life-time of the persons in whom it existed. With the exception of M. Bally's case, and that of the soldier reported in the *Annales de la Médecine et de Physiologie*, I do not know that it has ever been so much as suspected, either by the persons themselves or by their physicians*. That the heart beats beneath the left breast is, however, a fact very popularly known; and it might be expected that any strong pulsations of that organ, such as all persons must sometimes experience under the influence of violent exercise, mental emotion, or bodily disorder, would excite attention, and perhaps alarm, if they were felt on the opposite side of the body. It is less surprising that medical men have not oftener detected this peculiarity of structure. Several of those who were examples of it, appear to have died by violence, or after short disease; and even had they been submitted for some time to medical observation, the true position of the viscera was not likely to be ascertained prior to the invention of the method of auscultation. John Reid suffered no affection of the chest, and no particular examination of that part was made. I imagine, however, that a person versed in auscultation could scarcely fail to satisfy himself respecting the nature of such a case, if once his attention was called to it. It is not enough that the heart can be felt or heard beating on the right side of the sternum; that phenomenon is frequent, as the result of disease, and then denotes a *displacement* of the heart; and it is not unknown as a consequence of malformation, in the strict

* I have been recently informed by a student of King's College, that he had found the thoracic and abdominal viscera transposed in an acephalous kitten. There is a passage in Galen which seems to prove, not only that the ancients were aware of the occasional existence of heterotaxy in the human body, but that they had met with it still oftener in brutes. Ἡπαρ (he says) *προς τουτοις ολιγων μεν επι ανθρωπων, ουκ ολιγων δ'επι αλλων ξωων επιλαμβανειν αυτο των αριστερων μερων αληθως εγραψεν* Ἡροφιλος, *εν αυτῳ τουτω τῳ βιβλιῳ τῳ δευτερῳ των ανατομικῶν.* —C. 8. l. 6. *de Anat. Administ.*

* See additional remarks, p. 403.

sense of that term. Breschet and Otto have described several examples of this anomalous position of the heart, in persons whose other viscera preserved their natural places; and the elder Hoffman's very curious and learned little tract, entitled *Cardianastrophe*, was written to commemorate a like event. On the other hand, there is in the Museum of St. Bartholomew's, a specimen of transposition of the aorta and inferior cava, every thing else being as usual. The aorta lies on the lumbar vertebræ inclining to the right, and the vena cava to the left. Then, to reach the under surface of the liver, the vena cava, in the upper part of the abdomen, crosses over the aorta.

The circumstances which would guide us to a true conclusion are the following:—

1. The occurrence of pulsation on the right of the sternum, in the place and manner corresponding to what is ordinarily observable of the pulsation of the heart on the left.

2. The emission of a resonant sound, under percussion, from the part commonly occupied by the heart on the left side, and the existence of the respiratory murmur in the same part. This is necessary to show that the heart is not simply thrust out of its proper place, by a collection of fluid in the left pleura.

3. A dull sound elicited by percussion over a considerable space in the left hypochondrium; marking the place of the liver there.

4. A tympanitic sound, varying in degree, and perhaps not constant, in the right hypochondrium; denoting, not merely the absence of the liver, but the situation and varying conditions of the stomach.

5. Pulsation of the abdominal aorta felt upon the right side of the mesial line.

If these several signs were ascertained by carefully repeated examinations, no reasonable doubt could remain. In males, some confirmation might be obtained from the greater length of the spermatic cord on the right side: a circumstance very unusual, I believe, under the ordinary formation.

It would be interesting to learn whether the variety be always, or ever, derived to the child from the parent; but upon this point no satisfactory inquiries have yet been made. It has been ascertained, however, in several instances, that other children, born to the same parents, possessed the normal structure. I saw and examined one of Reid's brothers, and found his heart beating under his left breast.

More than one of the subjects of this change happen to have been notorious malefactors, and to have ended their lives upon the scaffold; and hence seems to have arisen the fantastical speculation, that as in them the mechanism of the body was crossly modelled, so, by some sinister and mysterious sympathy, the mental constitution also may have been warped and perverted, and the physical prodigy have been necessarily combined with moral deformity.

If a notion so preposterous could merit a serious refutation, it might be found in the fact that many of the persons similarly fashioned were but little remarkable in their lives, either for good or for evil; while one of them, at least, as we learn from the interesting statement of Sir Astley Cooper, was distinguished for active benevolence and kindness of heart, and passed through a long life in uncommon freedom from the vices most incident to her social station.

Since the foregoing paper was read, I have been favoured with several communications upon the subject to which it relates. Some of these it is proper that I should mention.

Mr. Stanley has pointed out to me, that in the body examined by himself, the most interesting and decisive circumstance, in relation to the completeness of the transposition, was, that the *thoracic duct* presented no deviation from its usual disposition, but took its ordinary course through the chest to its termination in the left side of the neck.

It appears *probable* that the thoracic duct entered the veins on the *right* side, in Sir Astley Cooper's case.

Mr. Stanley observes, that the question of the superiority of the right arm might connect itself with the consideration of the comparative developments, and of the liabilities to disease, of the right and left sides of the body. The following remarks, which occur in a course of General Anatomy, delivered in Paris during the last winter, by M. Serres, furnish matter of interesting speculation:—

"La loi de prédominance du côté droit sur le côté gauche s'applique à tous les organismes.

"Les organes surnuméraires se trouveront de préférence sur le côté droit, tandis que les parties atrophiées, ou même complétement anéanties, siégeront sur le côté gauche.

"Suivons dans la pathologie l'application de ces vues physiologiques sur la prédominance du côté droit sur le côté gauche. Vous verrez sur 20 coxalgies, 18 au moins siéger à droite, et 2 peine à gauche. Chez les enfans dont les testicules ne sont pas descendus dans le scrotum, vous trouverez vingt fois l'arrêt du testicule gauche, et une fois à peine celui du testicule droit."

I am further indebted to Mr. Stanley for the knowledge of three more instances of heterotaxy, observed by M. Scoutetten, and recorded in the *Journal Universel* for April, 1823. I transcribe the following summary account of them from the *Edinburgh Medical and Surgical Journal* for October in the same year:—

"I know not," says M. Scoutetten, "whether I have been favoured by chance, or whether visceral transpositions are more frequent than we generally imagine; but it is remarkable that I have met with three examples of the kind in less than a single year." All the subjects were young soldiers, who had passed their 20th year, were of a good constitution, and enjoyed excellent health till they were cut off suddenly by gastro-enteritic inflammation. In one of them the transposition of the chief viscera *had been detected during life.* The anatomical details present nothing remarkable, except the extreme precision with which the viscera of the opposite sides occupied the places of one another. The arteria innominata supplied the left arm and left side of the neck; yet one of the men was well known to be right-handed. In all of them "the vertebral column turned the concavity of its lateral curvature to the right instead of the left side;" a fact which Scoutetten thinks will contradict the notion of Bichat, that the ordinary curvature of the spine to the left side depends, not on the situation of the aorta, but on the habit of using most frequently the right hand.

Dr. Merriman informs me, that he is at present acquainted with a young woman, in whom this transposition exists: the heart pulsates on the right side, and the liver is palpable on the left. This female was a patient of the late Dr. Nuttall, who discovered the transplacement. She dislikes the notion that she is differently formed from other people, and is therefore unwilling to be questioned upon the subject; but she has permitted Dr. Merriman to make the requisite examination, and he has satisfied himself of the justness of Dr. Nuttall's opinion.

Some of the statements contained in the preceding paper require, therefore, to be altered.

Thus, instead of 29 examples of heterotaxy, I am now able to adduce 33. Among these there are still 8 in which the sex is uncertain. Of the remaining 25, 19 were males, and 6 females.

Also, I have now to add two (making four in all) to the instances in which the anomalous formation was detected in living person.

A CASE OF COMPLETE TRANSPOSITION OF THE VISCERA.

To the Editor of the Medical Gazette.

Sir,

I beg to transmit to you the notes of a case of complete transposition of the viscera. If you deem them sufficiently interesting, you will oblige me by inserting them in your journal.

I am, sir,
Your obedient servant,
Henry Snowden.

Hull, June 8, 1836.

Joseph Parker, aged 15, was admitted into the Hull General Infirmary, April 7th, 1836, under the care of Dr. Bodley, for tuberculous disease of various organs. He died on the 25th of May. The body was inspected thirty hours after death, in the presence of Mr. Huntington, one of the surgeons of the hospital, Mr. Higson, the house-surgeon, and several pupils.

The morbid appearances were such as are usually connected with tubercular depositions; they require no particular notice. But the case was interesting, in presenting to us an example of that altered position of the viscera which is termed "lateral inversion." In the thoracic cavity, the heart and the two-

lobed lung were on the right side; the three-lobed lung on the left. In the abdomen, the liver, with its gall-bladder, occupied the left hypochondriac region, stretching into the epigastrium; the spleen and the great *cul-de-sac* of the stomach were in the right hypochondrium; the œsophagus, passing downwards from the pharynx, inclined to the right side; the first portion of the duodenum ascended from right to left,—the third portion, passing across the spine, terminated in the jejunum on the right side of the second lumbar vertebra; the ilio-colic valve was placed in the left iliac fossa,—the sigmoid flexure of the colon in the right; the greater extremity of the pancreas was towards the left side.

The same uniformity of transposition was observed in the vascular system. As the heart was on the right side of the thorax, so its axis inclined to the same side; the ventricle, which is usually termed right, or anterior, was on the left side, and posterior, occupying the situation of the aortic ventricle, which was to the right, and anterior; the aorta, after its origin, inclined to the left side, but opposite the second cartilage of the ribs, turned from left to right, and continued its course downwards on the right side of the spinal column; the usual number of vessels arose from the arch; the arteria innominata passed to the left side; the vena cava ascendens was on the left side of the spine.

In conformity with the altered position of the large trunks, the distribution of the various branches passing to and from the viscera was changed relatively: the recurrent branch of the pneumogastric nerve was given off on the right side round the arch of the aorta, on the left round the subclavian artery. In fine, the most perfect adaptation was observed throughout.

This case is not unique: one analogous in every respect is related by Dr. Bryan, in the Transactions of the Dublin College of Physicians; another is recorded in the Transactions of the Royal Society of London for the year 1674. There is a preparation illustrative of a third in the Museum of the University of London: of this last, mention is made by Dr. Quain, in his Elements of Anatomy.

TREATMENT OF SORE NIPPLES.

To the Editor of the Medical Gazette.

Sir,

Sore nipples, so often the source of much suffering and misery to the patient, and of serious annoyance to the medical attendant, may, in nine cases out of ten, be healed by the following simple method:—

The white of an egg to be mixed with an equal quantity of brandy, and well shook together in a phial; the nipples to be anointed with a feather dipped into it, until a sufficient coating is formed; and this must be repeated after every time the child sucks.

This coating will be found to protect the nipple when the child is first set on, until the lubrication of the child's mouth renders it no longer necessary; and this protection soon enables nature to effect a cure.—I am, sir,

Your obedient servant,

Edward Greenhow, M.D.
Of North Shields.

Lower Tulse Hill,
June 1, 1836.

CERTIFICATES REQUIRED BY LIFE-ASSURANCE COMPANIES.

To the Editor of the Medical Gazette.

Sir,

If the inclosed short correspondence, which I have recently had with a Life-Assurance Office, is, in your opinion, likely to interest the readers of the Medical Gazette, I beg to place it at your disposal, with a request that you will substitute initial letters for the name of the office, of its corresponding clerk, and that of the gentleman whose health was the subject of inquiry.

Passing by, without comment, the impertinence, and injustice likewise, of the concluding paragraph of the official letter, and the prolixity of the series of questions attached to it, I would solicit your attention to the especial purpose for which professional men are applied to by Insurance Offices, as upon this point the whole matter in dispute between them essentially turns.

Is it, in fact, a mere recognition of

the identity of the party proposing to insure, and a testimony of his general well-being and becoming habits of life, that the medical referee is requested to give, and therefore his reply to the inquiry may, with propriety, be considered as an affair of courtesy only; or is the negociation which is carrying on between the parties, mainly dependent, for its satisfactory completion and the terms on which it is finally arranged, upon the information and opinions which he is solicited to give? If the latter is the case, as may be inferred from the very tenor of the questions put to him, the discussion is still further narrowed to the consideration of which party derives more advantage, and has its interests best served, by full, unreserved, and well-advised answers to them; and is consequently bound, in justice, to give an *honorarium* for the trouble and responsibility which they necessarily involve.

The person insuring, seeks to secure a certain sum to his representatives on the contingency of his death; which object the policy effects, however shortly after its signature his death may happen to take place; and while living, it is to his interest also to have but a small rate of premium annually to pay. The insurer, therefore, is desirous of having his life accepted upon the terms of a select life, and any testimony having a tendency to depreciate its value will be to his disadvantage. The professional referee can consequently serve the insurer, only by painting him *couleur de rose*.

The Insurance Office, on the other hand, conducts its business with a view to profit, and this is equally the case, whether it is founded on the principle of mutual insurance or otherwise, and profit can alone result from the insurer living beyond the estimated period at which the accumulated premiums and accruing interest together exceed the sum insured. To ascertain if the life in question is likely to attain this age, becomes, therefore, an object of especial importance to Insurance Offices, and a sense of this induces these establishments to investigate, not only the present state of health of the party, which their medical advisers could do on their behalf, but to ascertain, moreover, what previous illness the party may have had, and what particular predisposition to disease he and his immediate family connections may have given evidence of, and on the latter points the professional man, habitually consulted by the insurer, can alone give satisfactory information; and when in addition he is requested to give his "opinion" on this point, and his "opinion" on that, to deny him a fee for his services, is as unjust as it is impolitic.

Upon the impolicy of this proceeding I have on another occasion expressed my sentiments without reserve, my experience as a medical officer to a large Life-Insurance Company has given me very numerous proofs of it; and I have felt the truth so strongly, that I was induced some time since to advise the Office with which I have the honour to be connected, to present a fee to the medical gentleman they referred to. The plan I have proposed as, in my opinion, adapted to meet the case fairly, and with due consideration for the protection of the Office from fraud and unnecessary expense, is this: to require a guinea to be deposited with the "declaration;" this sum to be accounted for, and be deducted from the first premium paid, if the life be found insurable, and to be forfeited if considered uninsurable, the Office having been subjected to an equal expense in the reference of the case to its own medical officer.

I remain, sir,
Your obedient servant,
JOHN RIDOUT.

10, Montague-Street. Russell-Square,
June 7, 1836.

"M——— Life Assurance Society,
11th May, 1836.

"Sir,—A proposal having been made to the M——— Life Assurance Society, to effect an assurance on the life of Mr. B. W. L., and the Directors having been referred to you as his usual medical attendant, for information as to his general state of health, I am desired to request that you will, as early as convenient, favour them with answers to the several questions annexed.

"I beg to inform you, that any communication you may be pleased to make will be considered by the Directors as strictly confidential, and will not in any way be suffered to transpire.

"Should the Directors not have the pleasure of hearing from you before the expiration of ten days from the date of

this letter, they will conclude that you decline answering from your not considering the life eligible for assurance.

"I am, sir,
"Your obedient servant,
"H. M.
"Chief Clerk.

"*John Ridout, Esq.*"

[Here follows a string of twenty questions.]

(COPY OF REPLY.)

"10, Montague-Street, Russell-Square,
May 13, 1836.

"SIR,

"I have had the honour of receiving a letter from you, of the date of the 11th instant, requesting me to answer numerous inquiries relative to the health of Mr. L——, for the information of the Directors of the M—— —— Life-Assurance Society.

"I beg you will favour me by acknowledging to those gentlemen my receipt of their communication, and by expressing also my readiness to afford them the assistance they solicit of my opinion on the various points specified in your letter, upon my receiving an assurance that I am consulted by them professionally.

"I have the honour to be,
"Your obedient servant,
"JOHN RIDOUT.

"*To Mr. H. M.*
Chief Clerk."

MEDICAL GAZETTE.

Saturday, June 11, 1836.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE MEDICAL CHARITIES OF IRELAND.

IF it be true, as we verily believe it is, that a fair estimate may be formed of the civilization of any country, and of its proper position in the social scale, from the state of its medical institutions, what an idea must we entertain of the condition of Ireland. Half civilized, half savage, it presents to the view of the reflecting observer a picture which cannot easily be forgotten: it exhibits in some parts a species of chaotic confusion, the like of which can perhaps no where else be seen.

Until we saw Dr. Borrett's Report—a document which we are sure many of our readers have perused with much interest—we had no notion of the real state of those establishments, called *charitable*, in the sister kingdom: a vague impression was all that dwelt upon our minds—a persuasion that all was not right in that quarter: but the evidence afforded by our correspondent is explicit and complete, displaying a state of things which cannot be too fully exposed to public censure. The rest of Europe perhaps does not afford a parallel to the vile trickery and jobbing, the private intrigue and peculation, practised in many parts of Ireland, under the deceptive guise of ministering to the work of charity. Some few redeeming exceptions may of course be pointed out, but nothing to that extent which would alter the general impression just now mentioned.

Let us take the Dispensaries in the first place. Miserable as is the portion of relief usually afforded to the pauper classes by these institutions, it is found to be most deplorably marred and curtailed by the practices pursued by the managing parties in some districts. Persons frequently get up establishments of this kind for their own private purposes, and no sooner attain their object, than they are guilty of the grossest neglect of duty—in many instances, it is to be feared, of palpable peculation and fraud. Any sort of place seems to serve for the locality—an outhouse—a stable—a filthy barn in a state of dilapidation—in short, anything resembling a covered inclosure: and here the medicines are stowed. Sometimes little else is to be seen in the shape of medicine than a cask of Glauber salts, or a quan-

tity of castor oil; but commonly no more of these, or other articles of a like description, than can be contained in a small cupboard. We must give Dr. Borrett's description of what he saw in some of these precious pharmacies:—

"At Freemont, Elphin, Maynooth, &c. the medicines were spoiling from damp; and, in some instances, not only were no pains taken to preserve them, but the room in which they were kept was in a dirty and slovenly state, or the building in a ruinous condition. This was the case at Tulsk Dispensary, where, owing to the wet dropping from the rotten thatch, or driving in through gaping chinks in the mud-walls, and the wretched condition of the interior, the few ordinary drugs which were found jumbled together in the drawers of a musty press, proved, upon inspection, damp and damaged. At Oyster-haven, the filthy outhouse, which was used for the Dispensary, contained scarcely a pound's worth of medicine. And at Ballyleague, with the exception of some half-dozen shelves put in the corner of the room opposite to that in which the bed lay, there was no arrangement for the Pharmacy—no fittings-up of any kind, neither drawers, cases, nor counter—no apparatus for compounding and dispensing medicines —nor any instruments, weights, or measures. Of the pots and bottles with labels on them, which stood upright on the shelves, many were found, on inspecting them, to contain merely the mouldy remnants of drugs, whose virtues were gone long since, many more to be empty, and others again, where it was possible to recognise their contents, had been misrepresented by the inscriptions set upon them. Three or four packets alone, containing medicines of the common kind, were of a good description: but the greater part of such stock as the establishment possessed, lay strewn upon the ground—bottles, gallipots, jars, and other utensils, mixed with sundry parcels of drugs, lumber, and rubbish. Nevertheless the annual charge for medicines, upon an average of the last three years, amounted to little short of 50*l.*, a sum sufficient for providing an excellent supply of medicines, but which, it would seem, had been applied in part, if not chiefly, to purchasing sundry jars of oil, vinegar, and molasses."

Of the mode in which the medicines are supplied in some places we have also an account. The medical officer, who is generally an apothecary residing in the neighbourhood, and using his shop, on the appointed days, as his Dispensary, is occasionally allowed to charge a specific sum for drugs.

"Sometimes no distinction was made between the stock of private medicines for sale, and those belonging to the institution: or the latter sort were stowed away in the corner of a shop, kept by the medical officer, while those he had upon his own account were well appointed and arranged, and ostentatiously displayed, which led to the impression among the poor applicants, that they had better pay a something for a good article than put up with a bad one. But not only was the trick resorted to of giving the public clearly to understand from appearances, that if they wanted good medicines they must purchase them at the shop, but the fraud was committed of selling the medicines belonging to the Dispensary without putting the money thus obtained to the credit of the charity. I mention this fraud as having been detected, although but in a very few instances; I by no means wish to imply that it was common, or to cast any imputation of the kind upon the medical attendants in general; and I wish as much to be understood when I state, there was at times strong reason to suspect that the pharmacy had been dressed up for the occasion of the visit of the Assistant Commissioners, and drugs procured for exhibition, but which did not belong to the Dispensary."

Where such arrangements are made for dispensing *medicine* to the poor applicants, the *advice* can scarcely be expected to be of a much better description; nor does it seem that regularity of attendance is much practised, or considered very essential. The abuses altogether, we must say, are of a crying nature; but, perhaps, not wholly owing to the conduct of the medical men.

A vile abuse, probably to be found more or less connected with most medical establishments supported by subscription, is carried on in some of the Irish Dispensaries to an enormous extent: we mean the misappropriation of the funds and resources of the institution, in relieving others than the proper objects of the charity. Wealthy farmers and others subscribe, and expect to have, nay insist on having, their children attended during their illnesses, without giving the practitioner any additional remuneration; they think their mite contributed to the Dispensary quite enough. Who can wonder that medical men, thus treated, should soon become negligent of their duties, or that instances should often occur of wretched patients dying for want of the requisite attentions?

It is a most distressing subject for the contemplation of the humane mind, but examples of wretched creatures perishing for want of necessary assistance, are, it seems, fearfully frequent in Ireland. In no other country professing to be civilized, could such instances as those mentioned by Dr. Borrett, in the following passage, be met with. In consequence of the inadequacy of medical relief, and the want of a little accommodation about the Dispensaries, "painful instances," says Dr. B., "have occurred of late, in which persons seized with fever, or cholera, or to whom an accident had befallen, were obliged to be abandoned to their fate—left under a hedge, or in a ditch, or pit, by the road-side, to perish—because there was no place to take them to. If a wandering beggar was taken sick, he had no alternative, in several places, but to lie in the open air. Sometimes the poor would build a hut over him. A man, seized with the cholera, at Bantry, after lying all day in a boat, was put into a store, where he died. A woman, attacked by the same disease, had expired in a ditch!" A bed or two attached to each Dispensary, in order to meet such emergencies, would, in the opinion of the Assistant Commissioners, have prevented all this terrible sacrifice of life.

But it may be said that these were cases more suited to the County Infirmary or Hospital, than to the Dispensary. So they were: but those establishments were afar off; and even though they were nearer, it is not quite certain that they would have been found available in the cases described.

The Irish County Infirmaries, it appears, exclude cases of febrile and internal disorder: they are destined wholly for the treatment of surgical maladies; and even where large infirmaries are established, and many of the beds occupied with patients who could just as well be attended at their homes, Fever Hospitals have to be erected in addition. There are many points connected with these Infirmaries, to which the public attention ought to be more strongly drawn. Of the monopoly in the appointment of the medical officers, possessed by the Irish Coleges of Physicians and Surgeons, we have formerly had occasion to speak; and we are glad to find that Dr. Borrett's view of the case accords with that taken by every unprejudiced and disinterested person. The restriction which secures these County establishments for the members of the Colleges just mentioned, might have been necessary at the time the act of parliament to that effect passed; but sixty or seventy years have since gone by, and there can be no sufficient reason assigned for any longer maintaining so very objectionable a monopoly—excluding, as it does, every surgeon who holds the diploma of the London, Edinburgh, or Glasgow College,—that is to say, the great bulk of the surgical profession in Ireland.

It is not to be denied that some of the

County Infirmaries may be well conducted, and their medical officers men of zeal and ability; but the plan of those establishments has in it much that is radically faulty, and which greatly cripples their usefulness to the public. We have seen that Fever Hospitals have in many instances to be raised in order to meet the ordinary emergency of acute internal maladies; while there can be but little doubt that the object desired might be more economically and conveniently effected, as Dr. Borrett suggests, by converting the two establishments into "one general hospital for the reception of medical, as well as surgical, cases." Physicians and surgeons might then be alike appointed, the beds distributed between them, and all truly necessitous persons admitted, if seriously ill, even without the form of a recommendation, giving a preference always, of course, to accidents and fever cases.

Concerning the mode of managing the funds of some of these well-meant, but ill-organized, institutions, we have much valuable information in Dr. Borrett's Report. The North Charitable Infirmary, at Cork, is a *beau ideal* of the system, which we take to be one heap of abuses. In that establishment the apothecary is all in all—the trustees, treasurer, and governors, nothing.

> "On referring to the book of proceedings, it appears that scarcely any regular meeting of the governors has been held for the last forty years to elect trustees according to the provisions of the Act of Incorporation of 1774; and although this act requires that the accounts should be examined every month by five trustees, they seem for many months together to have been entered in the book at the same time, and frequently in the presence of only one, and seldom more than two, trustees. Indeed, no other signature is to be found in the account-book for several years in succession than that of the late surgeon, who was also a trustee."

The Assistant-Commissioners made two attempts to meet the said trustees at stated times of meeting: but only on the first occasion did they succeed in seeing any one—when they saw the apothecary's son-in-law! It may well be imagined in what manner the affairs of such an Infirmary must be conducted: the details are given in the Report of Dr. Borrett. The *South* Charitable Infirmary seems to be, in every respect, a contrast to its unfortunate brother.

The Lunatic Asylum of Cork must not be passed over in silence: it is, perhaps, one of the most valuable institutions in the province of Munster. We believe that, generally speaking, the Lunatic Asylums throughout Ireland, or at least many of them, principally those in the neighbourhood of the larger towns, are excellently well appointed. Of the one in Cork, we are told, that it contains between 300 and 400 patients, at an annual expense of somewhat above 4,000*l*., and the present physician, it appears, has introduced certain improvements into the management which entitle him to the best thanks of the community.

We cannot at present pursue this subject further: but we once more take leave to recommend Dr. Borrett's report, and particularly that gentleman's Supplementary Remarks and suggestions, as published in our last number. We have only to observe, in conclusion, that if something be not done, and that speedily, to reform the Dispensary system, and much that is connected with the County Infirmaries in Ireland, permanent disgrace must attach to the whole medical body in that country: for the circumstances are now precisely known, and the public will not be slow in forming a decided opinion. The difficulties that stand in the way, and which must be previously removed, are indeed obvious enough: we can very well conceive the stubborn nature of the task which they must grapple with who would attempt to place the Irish on the same footing

as the English Dispensaries: the mass of the people of Ireland labour under destitution and distress; and what is worse, under despondency or recklessness, as regards the possibility of bettering their condition. Such beings must be looked after by others: they cannot be expected to make the least exertion for themselves.

Let, then, the intelligent and humane endeavour to produce a better condition of things; and above all, let the members of the medical profession come to an understanding as to what steps are best to be taken. We venture not to point out the particular measures which it might be most prudent to adopt; but we strenuously recommend the union of the profession in Ireland for improvement and counsel sake. Why, we ask, is there no Provincial Association formed in that country, similar to the excellent one already established here? But on this important point we shall reserve our further remarks for another opportunity.

THE PLAGUE RUMOUR.

Although the silly report that the plague had broken out in London has been officially and very satisfactorily contradicted, we think it right to record the total absence of any thing like a rational foundation for the alarm. How long the rumour might have existed, and what degree of panic might have been excited, it is impossible to say, had not the party who acted as *accoucheur* on this occasion sent to require the assistance of Mr. Poulett Thomson, by which means the monstrous fabrication was strangled in its birth. Sir William Pym was instantly dispatched to examine into the facts, when, behold! certain events which had been confidently stated to have occurred, were discovered to have had no existence whatever but in the overheated and busy imagination of the writer. We trust the party in question (whose name, by the way, is no secret in the medical circles) will be more careful hereafter, else may ridicule not be the sole consequence of his indiscretion.

CLINICAL LECTURE

ON

EXCISION OF POLYPUS UTERI.

Delivered at the Middlesex Hospital.

By Mr. Arnott.

I. *Large thick-necked fibrous Polypus.*

For the removal of polypus uteri, the treatment recommended by Clarke, Gooch, Merriman, and other writers in this country on the diseases of females, is the application of a ligature; and the same doctrine is, I find, inculcated by the lecturers on midwifery. You have lately witnessed another mode of proceeding, and I now revert more especially to the case of Ellen Harris, because it will afford me an opportunity of again directing your attention to the merits of the treatment of polypus by excision, and as it is a good example of the effects and symptoms of the disease. It has shewn also, what difference of opinion may sometimes be entertained of the nature of a growth from the womb previous to its removal.

When she sought admission into the hospital, this woman presented a most wretched appearance. She was extremely emaciated, her countenance bloodless, with a sallow colour, waxy appearance, and haggard expression. She was so weak as hardly to be able to support herself, indeed she only did so by leaning on the arm of a friend, and when she thus came into the admitting room, stooping in her gait, she walked slowly with apparent difficulty and somewhat straddling, and brought along with her a strong urinous odour. To the inquiry of what was the matter, the reply was, that she could not hold her water, and from this answer, her appearance, and the circumstance just mentioned, I suspected that I should have to deal with a case of incontinence of urine from cancer of the womb. But on taking her into the adjoining room, and making the necessary examination, a very different condition of disease presented itself.

On passing the hand towards the vulva the perineum was felt distended, protruded by a large tumor which filled the vagina, and a portion of which, like the vertex in natural labour, shewed itself at the entrance of the passage. The tumor felt firm, fleshy, somewhat irregular, but with a smooth surface: the exposed portion of the size of a crown-piece, had a dark purple almost livid colour, and at one spot was grey and pulpy. There was a copious, sanious, offensive discharge from the vagina; the skin of the labia and perineum was red, and the inner surface of the former somewhat excoriated. This cast, by

M. Talrich, taken the day after the patient's admission, gives a good representation of the external appearances.

Examination gave very considerable pain, but the finger could be carried all round the swelling in the vagina, to which it was not attached except at its upper part. To ascertain the nature of this attachment, the finger required to be passed to its utmost extent, the vagina then was at least of its natural length, and the tumor could not be occasioned by prolapsus uteri, whereby this canal is shortened. The bulk of the swelling was ovoid, but it got narrower above, though still of the thickness of my wrist as high as could be reached. What was it? It must either be a growth from the womb, or that organ inverted. Now the circumstances which chiefly guide us in determining to which of these classes a tumor in this situation belongs, are taken from its sensibility and the history of the case, for there is nothing in the form of the tumor, and, speaking generally, in its relation to the os uteri, essentially distinctive. The inverted uterus possesses common sensibility, and the recurrence of the disease follows almost invariably upon labour. In our case the tumor was pressed and squeezed, and its surface scratched by the nail without the patient being conscious of any of these proceedings. Examination gave pain it is true, but this arose from the inflamed state of the passage, and you will recollect, that when my finger was in the vagina, I called your attention to the fact, that whereas pressure directed towards the parietes of the pelvis caused the patient to cry out, yet on this being directed towards the tumor she did not seem to feel it. The history of the case, too, was not that of inversio uteri but of polypus.

She stated that she was 47 years of age, and the mother of seven children,—the last after a premature labour, six years ago. About four years since she was attacked with what she calls "flooding," which continued for more than a month; and she has ever since menstruated in larger quantity, with clots and pain. For the last six weeks the discharge (sanguine) has been constant. During this period, in making use of the *pot de chambre*, she has had difficulty in rising from it, always feeling as if there was something more to come away. Until Thursday last (six days ago) she has been able, though greatly reduced, to get about; but on the evening of that day, feeling an inclination to make water, she could not, and in straining involuntarily for this purpose, half a potful of blood suddenly flowed, she says, from the back passage, around which, it may be mentioned, were several large piles. During Friday she experienced a constant inclination to make water, but without avail, as she sat on the pot. The only way in which she obtained relief was by sitting on the edge of the bed, so as to press on the perineum and posterior part of the vulva, leaving the anterior part projecting and exposed. By this proceeding small quantities of water were evacuated; and whilst she lay in bed some flowed involuntarily. The urine does not now come freely, but more so than it did. The bowels have acted regularly. Complains greatly of soreness of the vulva.

All the symptoms described in this statement might be accounted for by an inversion of the womb, as well as by a polypus: the menorrhagia first, the continued discharge afterwards, the impediment to the passage of the urine, and the partial relief obtained by sitting on the edge of the bed, so as to press on the perineum, and thereby force the tumor somewhat upwards, and in some measure off the meatus urinarius and urethra. But the important circumstance, in a diagnostic point of view, was the period of their commencement, and that some years after labour, thereby confirming the opinion already deduced from the want of sensibility of the tumor, that it was a case of polypus, and not of inversion.

Being a polypus, what were the relations of its stalk to the os tincæ and neck of the uterus? From the great size of the tumor, that of a pine-apple, or of one of my fists with the other hand clasped over it, and the shortness of its stalk, and being wholly contained in the vagina, it was with difficulty that the os uteri could be got at; and then only on the left side, where its lip, to me apparently healthy, could be felt surrounding this part of the stalk; elsewhere it was so high, that it could not be reached.

Polypi of the uterus are of varied nature; but from its firmness, from its form, and from its size, I was satisfied that the polypus in this case was one of the fibrous kind, or that texture identical with, or very analogous to, the fleshy tubercle of the uterus. But a very different opinion was entertained of its nature by some gentlemen familiar with diseases of the uterus: from the general character and expression of the patient's countenance, from the fœtid offensive discharge, from the dark colour of the tumor where it was exposed, from its knotty feel, from the soft pulpy condition of a part of the surface, and from the habitual soreness and pain when she was examined, it was suspected to be malignant.

Now the countenance was undoubtedly most unfavourable; but bad as it was, I told you at the time that I had seen countenances equally sallow, waxy, and hag-

gard, from continued discharge and simple polypus uteri, without malignant disease. So also with regard to the offensive discharge; wherever you have blood putrefying in the vagina, and uncleanliness, you may have this. The dark colour of the tumor I attributed to blood gravitating to its lower part; and the soft pulpy part was merely a small superficial spot in a state of slough. The fleshy tubercle has not uncommonly a rugged surface, but then it rarely ulcerates: moreover, I have never seen a malignant growth of this size not ulcerated. For an instant a large tumor being felt above the pubis, created a suspicion that there was malignant disease here, either of the womb or ovaries; but on introducing the catheter, upwards of two quarts of water were drawn off, and all swelling here disappeared. The bladder had no doubt been distended for some days, and only the surplus discharged involuntarily, or in consequence of the manœuvre of the patient you have heard described.

The question of treatment now presented itself, and I resolved to excise the polypus, as the *safest* and *most expeditious* mode of proceeding, and also, I believe, the least painful. I say safest and most expeditious; for supposing you had applied a ligature in this case, what were the circumstances, and what was to be dreaded. From the great thickness of the stalk, and its firmness, the ligature would have required a number of days, probably ten at least, to cut its way through; and, during all this time, you would have a putrefying mass in the vagina, which was already irritated and inflamed; and this in a constitution greatly reduced, little therefore able to bear continued irritation, and greatly disposed to suffer from the absorption of purulent matter. I know that there is an idea that the employment of the ligature is a very safe proceeding, and very easy of application. We will grant that it is generally safe; and yet, on close inquiry, I find that even those who use it, acknowledge that cases have occasionally been met with where the ligature, in cutting its way through, has excited irritation and fever, and even death. Two cases have been described to me by the practitioners concerned where this occurred, and, on casually referring to the interesting works of Boivin and Duges, I find two similar ones. In these four cases the ligature was applied to the stalk of the polypus.

With regard to the facility of the application of the ligature, the number of contrivances for effecting this does not coincide with the idea of its being quite an easy thing to do it effectually; but even granting that we have now got in this double canula an instrument for doing so, you need not go far to find evidence that we do not thereby secure accuracy of application. In Dr. Gooch's book, for instance, you will find a case described which occurred in St. Bartholomew's Hospital, and where he seems to have been the operator, when, with the double canula, the ligature was applied to the neck of the uterus instead of the polypus, and death was the result. This is not an isolated instance.

Now, in comparing excision with the ligature, it may be said that the accident last alluded to might occur with the use of the knife or scissars. No doubt it may; and yet I cannot help thinking, that where surgeons employ cutting instruments, they are more likely to ascertain accurately what they are about to divide, than if they use a ligature, which is supposed to be a more innocent affair. Indeed, the chief reason why the ligature has been employed, has, no doubt, been the security it is supposed to afford against hæmorrhage; a security which the practice of the French surgeon, Dubois, has shown not to be infallible. It is the dread of this hæmorrhage, too, which has prevented the general adoption of excision; a dread which is by no means justified by experience. I have never removed polypus uteri otherwise than by excision; and when a pupil at the Hôtel Dieu, I have seen a number extirpated in the same way, and always without hæmorrhage. But the experience of Monsieur Dupuytren, who probably tried this operation more frequently than any other surgeon, is most conclusive on this point. In about 200 cases, he only twice met with bleeding to any extent; in both cases it was quickly stopped by plugging the vagina.

Seeing, then, that bleeding was not to be apprehended from excision, and that by this means a source of irritation which was threatening the patient's life would be immediately and at once removed, I think you will acknowledge the validity of these reasons for the adoption of the mode of operating resolved upon. Owing to some impediment on the part of the patient, the operation was deferred for a couple of days; during which, by the use of opium, wine, and beef tea, and the employment of decoction of poppies, as an injection to wash out the vagina, the condition of the patient, generally and locally, was somewhat ameliorated.

The urine having been drawn off by the catheter, and the patient placed on her back, as in the operation for lithotomy, without being tied up, the polypus was laid hold of by a pair of double-hooked forceps, and drawn downwards steadily. I then introduced my left fore finger beneath the pubis, so as to reach the os uteri in front, and then guiding below this the blades of

a pair of long curved scissars, I proceeded to divide the neck of the tumor on the fore part, by a succession of strokes, (I have already told you the neck was as thick as my wrist) taking care to guard against wounding the vagina as well as the uterus. The anterior part of the pedicle being thus divided, (and that without the patient's experiencing any pain from the division) the tumour could now be drawn over the edge of the perineum, thereby facilitating the division of the other part; for until this was effected, I could not feel the posterior lip of the os uteri, and without this I could not, satisfactorily to myself, complete the section. You will understand the reason of this when I state to you that where a polypus is attached to the cervix and os uteri, the line of division between the two may not be readily perceived, and that the uterus might be cut instead of the polypus, if the operation was carelessly executed. On afterwards introducing the finger into the os uteri, the pedicle of the polypus was found to have been attached to the posterior part of the neck of the uterus, the mouth of which was, of course, of great size, and the lips were tumid and irregular, but not otherwise diseased.

Not a couple of ounces of blood followed the operation; and on visiting the patient in the evening, I found there had not been sufficient discharge to stain a napkin. The day after she was able to make water without the use of the catheter; in a week, the improvement in the patient's countenance, complexion, and feelings, was most striking, and in three weeks the os uteri was found to be restored to its natural size and healthy condition. The patient left the hospital restored to health.

On dividing the polypus, it presented a fibrous texture, of great firmness, but not so hard as the fibro-cartilaginous tumor of the uterus sometimes is. The upper part and middle of the tumor was of a whitish colour, the lower part was of a dark red, from the presence of blood, which occupied the surface, not the centre: it seemed to depend on congestion, probably venous. The section exhibited some tolerably-sized vessels. The small portion of the root left attached to the uterus, and the section of which presented the same fibrous structure as that just described, seemed to have withered, like the umbilical cord in the child, after it is tied.

II.—*Polypus Uteri from dilated Nabothian Glands.*

You have already heard that the majority of cases of polypus uteri are of the fibrous kind, but within the last few days I have had a case in the house, which proves to you that they are not all so.

June 1st.—Lydia Chapman, æt. 36, has had one living child, and a miscarriage. Thee weeks ago, her attention was directed to something protruding from the vagina, unattended by pain, or any disturbance in the uterine function, or in her general heelth. Subject to leucorrhœa, but her menstruation is not in greater quantity than natural. Examination displayed at the entrance of the vagina a whitish tumor, the size of a small pullet's egg, and with a perfectly smooth surface. It felt soft, as if containing a fluid, was pediculated, and on tracing its long and narrow neck, this was found attached to the anterior lip of the os uteri, but in no ways connected with the cervix.

The polypus being transfixed by a tenaculum and drawn down, the pedicle was divided by means of the curved probe-pointed scissars, on a level with the os uteri. Only a tea-spoonful or two of blood followed, and she has since done well. The cut surface of the pedicle was about the size of a fourpenny piece; it presented a mixture of white fibrous tissue, and one or two small cysts, containing gelatinous transparent mucus; and on making a vertical section of the tumor, it was found to consist of one large cyst, filled with the same thick ropy stuff, in quantity equal, perhaps, to three drachms. Here are the two halves of the growth, oval in shape, and, like an egg-shell, preserving their form from the firmness of their parietes; and the contained substance at the bottom of the glass. This polypus, then, is constituted by dilated nabothian glands, forming a striking contrast to the solid fibrous texture of the preceding case. The difference was as great in the symptoms: here there had been no menorrhagia, and the health or appearance was in no ways affected;—this important distinction no doubt mainly depending upon the tumor in the one case having never been in the womb, but only growing from its lip; whereas the other had originally been contained, and had protruded from within this organ. Both cases serve to demonstrate to you that excision of polypi is a safe and legitimate operation.

The operation is best effected by the scissars curved upon the blade, as I show you, and probe-pointed. It is not easy to employ a knife, or a bistoury, whatever may be its form, safely and effectually deep in the vagina.

But you may inquire if I recommend that these growth should be invariably excised? To which I reply, that I think that this ought to be adopted as the general method of operating. I do not mean, however, to declare that there are no cases in which the ligature should not be resorted to in preference; for although I have not witnessed any such, yet I can conceive a case in which this might be

proper: for instance, although the mere thickness of the stalk is no objection to excision,—indeed, it is here especially that excision has the advantage over the ligature,—yet, if on examination I felt some large vessels pulsating in the tumor or its pedicle (which I never have done), I would be disposed probably to resort to the ligature.

In a case analogous to the one I am now about to describe to you, from its interest and connexion with our subject, I would employ the ligature in preference.

III.—*Inversion of the Uterus from Tumor attached to the Fundus.*

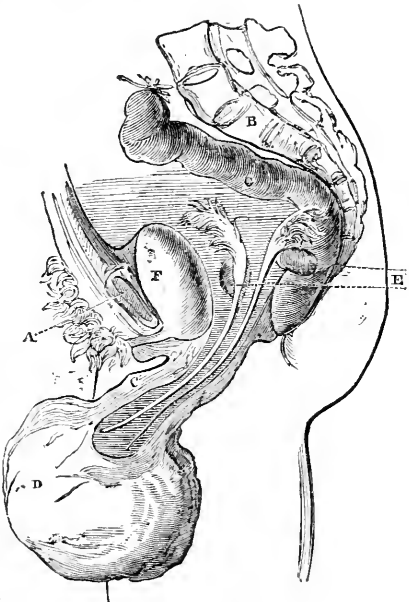
The cast upon the table was taken by Mr. Shaw, from a woman who died in this hospital some years ago, and the plan I now show you represents the parts as seen in the preparation preserved in spirits which I have examined; but I did not see the case during life. Mr. Shaw has favoured me with the following note:—

"The patient was under Mr. Bell. While she lived, the tumor was of very considerable size; when she came first into the hospital, it was more than three times the size of the cast taken after death. A consultation was called to determine on the propriety of an operation. If it were a polypus, where should the ligature be applied? The situation of the os tincæ could not be ascertained: the irregularity on the back part, which resembled it, had no canal into which a probe could be introduced. If the tumor had inverted the uterus, then would the operation be an extirpation of the uterus.

"In the meantime, the patient was full of irritation and complaint; and although she said her 'burthen' or her 'misfortune' was lessening (a consequence of perfect rest), yet she was evidently very ill, emaciated, sick, and distressed with abdominal pain. She died suddenly and unexpectedly at last; and the cause of her death was an ulcer in the right extremity of the stomach, with scirrhous contraction of the pylorus."

Here was a case of inverted uterus from a growth attached to the fundus, which first probably distending the womb, had, when it descended into the vagina, drawn down the fundus, the mechanism being the same as in the more frequent case, when the fundus is drawn down by rude and incautious traction on the cord or placenta after labour; for distension must apparently precede, in order to admit of inversion of the uterus.

There was, it appears, difficulty in deciding on the nature of the case during life; and on looking at the preparation where a section is made, it is certainly not easy to say where the growth (which has



A, Section of the symphysis pubis.
B, Section of the os sacrum.
C, The uterus, inverted and prolapsed.
D, Tumor adhering to the fundus of the uterus.
E, The two ovaria and the fallopian tube.
F, The bladder.
G, The rectum.

a cauliflower shape, and a broad attachment), terminates, and the substance of the uterus commences. Removal of the whole, including the inverted uterus, would necessarily have been attended with opening the cavity of the peritoneum, and therefore I conceive a ligature would have been the best method of operating. Here there would be an object in view prior to the removal of the tumor, and that is, adhesion of the sides of the prolongation of peritoneum, which is drawn down and lines the inverted uterus and vagina. If we could produce this with certainty in any other way, there would be little danger in then excising the map. But the ligature is the only mode which has as yet been tried, and although the proceeding is no doubt a hazardous one, it has been followed by success in cases of inverted uterus.

THE STIMULATING EFFECTS OF COLD WATER.

We find the following curious and amusing letter in the *Indian Journal of Medical Science:* the writer signs himself Davidson, Lakhnáu, April 21, 1835.

Sir,—I have lately read an account of a recovery from the effects of lightning by the application of cold water, in one of the numbers of your journal, and perhaps you will not object to the publication of the following circumstances, which may be relied on as perfectly free from exaggeration.

I was once called by my servants while at Asseergurh, to kill a large powerful snake that was seen on my farm yard. After a really desperate fight I killed a dhàman six feet long, and, as I then thought, smashed it brains to atoms with a heavy solid bamboo. I took it up in triumph, and carried it to the front of my bungalow: as I wished to preserve it, and it had become very dirty, I poured a gharràh of water over its head, when to my great surprise, it immediately began running down the hill, and I had to kill it over again. I believed that the reanimation had been caused by the application of the cold water. Returning from Bombay in 1823, I passed through the cantonments at Jalná, then occupied by Madras troops, I called one morning on Dr. Alexander, who was attached to the horse-artillery, and he told me that he had in that morning's ride rode down and killed a sickly wolf, with his hunting whip. I wished to see it, and was taken to the compound hedge, where the animal to all appearance lay dead. I said, "I'll make that wolf get up and look you in the face." Alexander laughed, and said that he had smashed it's skull with the heavy brass end of his whip, and trailed it lifeless after him for a mile or two. I still persisted that I could re-animate it. At last he said, "Very well, try." Some cold water was procured, and on its being dashed over the skull, the animal got up, rested on it's fore legs, and stared at us both with a most horrid glare! If Dr. Alexander be alive, he will probably remember his astonishment on the occasion.

In consequence of these and similar occurrences, I began to place great confidence in the power of cold water applied to the brain; and I will now relate, in my opinion, a very extraordinary circumstance, which shows that it was not without good cause. Soon after my return one of my chupprassees solicited permission to be absent for a few days for the purpose of visiting a large melá, or fair, held in the middle of a dark and gloomy forest twenty miles to the east of the fortress. Being fond of seeing sights, I determined to accompany him, and after having dispatched a tent, on the second day I rode to a village half way, and slept there during the night; next morning I reached the fair, which was held on an open spot in the centre of the forest. It was a festival in honor of one of those huge striding Hindù deities, who from the peak of the Himalaya placed one foot on a rock in the middle of the fair, and at another step stood on a mountain in Ceylon! There could be no doubt of the fact, as the impression of his foot was still visible on the rock; and it was visited once a year with great reverence by 150,000 innocent 'Hindùs.' Nothing occurred during the day, but in the night I was repeatedly awakened by a simultaneous and universal clapping of hands, in honor of the deity before mentioned, which in the stillness of the forest had a very curious and startling effect.

I got up at day-break next morning, and mounting my horse traversed the fair in all directions, at one time mightily tickled by observing faqueers lying naked on the thorns of the Babúl (most *carefully crushed*), and at another admiring the simplicity of the innumerable devotees who were crawling up and down the hill, to visit the sacred spot. On returning home I perceived at a considerable distance, on the skirts of the fair, two large mobs. I cantered up to the nearest, and instead of seeing some outrageously pious Hindù saint, observed a very stout and handsome young woman, of about 20, lying apparently dead on the ground. I quickly dismounted, and found no signs of life, but warmth of body. There was no pulsation at the wrist, temporal artery, heart, or ankle. On inquiry I ascertained that she had been lying two ghurrees in that state, having fallen down *suddenly* without previous notice or illness. Owing to the mob round her, the heat was perfectly suffocating, and I desired her husband, a grey-headed old man, to clear a large space round her for the sake of air, and I would try to cure her. This he eventually did, with the assistance of other men, but with great reluctance; as he said she had been so long dead that he *must take her to be buried.* She was a Mussulman. I proceeded to examine the body more minutely, and all that I could discover was, that the attack was not epileptic, but might be from spasm.

I called out for cold water, but as none was procurable, I dispatched my groom who brought my servants from my tent with a couple of large gharràhs meant for my morning bathe, which had been cooling all night. The mob was again cleared, and sitting down, I dashed water on the woman's head two or three times, still there was no symptoms of returning life. I tried again and again, and at last one of the eyelids twinkled. Delighted at this, I cleared the ground again, and uncovering her chest, I poured a whole gharràh over her body.

The effect was magical; she suddenly started up with a scream, wiped the water from her face, seized her dishevelled hair, twisting it behind her head, snatched her clothes, and looked round with a stare of astonishment. A loud shout of surprise rent the air, the miraculous cure of the feringee spread like wild-fire through the fair: accompanied by her sister and husband, I walked to my tent surrounded by a dense crowd of admirers! After seating the party in my tent, I rode off to the other mob, where lay the body of a boy of 10 or 12 years of age, surrounded by howling females. I knelt down and found his body also warm, but without pulse; I requested that the mob might be cleared, and offered to try my skill on him, and my request was backed by many who accompanied me from the first scene, but all in vain. I was obliged to leave the poor boy to his fate, and was returning to my tent, which I had scarcely reached, when I saw him carried past with his legs dangling in the air, to be, in my belief, buried alive.

I found my patient's pulse very languid, and therefore gave her a pint of old maderia at a draught, which, 'nothing loth,' she swallowed, just to give a *filip* to the circulation! She slept soundly till sunset, when, without once thanking me, she walked out of the tent.

The fair lasted two or three days after this, during which time I never left my tent without being followed by a mob, and I am persuaded that if I had felt inclined, I might have set up for a prophet without further capital, and procured a lakh of chelas in 24 hours. But you know that is not my vocation!

A year afterwards, when riding through one of the streets of Booraupoor, I overheard a conversation among some Mulsulmans, who were disputing who were the most learned, the Moosulmans or Feringhees? One vehemently backed the feringhees, and swore "Korán ki Kusum that there were none so clever, for with his own eyes he had seen one of them raise a dead woman to life." "Jhooth bát," said another. I laughed; the philo-feringhee jumped up, and roared out "Soobhán Ulláh, there's the sahib himself, ask him. Krores of people saw him do it."

Since that period I have repeatedly stopped fits of epilepsy in people found lying in the streets in different towns by the same means.

LECTURES

ON

MATERIA MEDICA, OR PHARMACOLOGY, AND GENERAL THERAPEUTICS,

Delivered at the Aldersgate School of Medicine,

BY JON. PEREIRA, ESQ., F.L.S.

LECTURE XXXVIII.

MERCURY—*continued.*

WE have in this lecture to examine the *uses of mercurials.*

Certain preparations of mercury (as blue pill, calomel, and the *hydrargyrum cum cretâ*), are employed as *purgatives.* They are rarely, however, used alone; being, in general, either combined with, or followed by, other cathartics. Thus it is a common practice to exhibit a blue or calomel pill at night, and an aperient draught the following morning, the object being to allow the pill to remain as long as possible in the bowels, in order that it may the more effectually act on the liver. Mercurial purgatives are administered for various purposes, sometimes as anthelmintics—sometimes to assist in evacuating the contents of the alimentary canal—but more commonly with the view of promoting the secretions, particularly of the liver, or of producing counter-irritation, and thereby to relieve affections of other organs, as the skin or head.

As *errhines* or *emetics*, mercurials are never resorted to now, though formerly the subsulphate was used for these purposes.

As *alteratives*, they are given in small doses in various chronic diseases; such, for example, as dyspepsia, gout, chronic skin diseases, scrofula, &c. Calomel is said to be less beneficial as an alterative than blue pill, on account of its more irritating action on the bowels. The *hydrargyrum cum cretâ* is an excellent alterative.

They are frequently given so as *to affect the mouth*, or to produce *salivation.* Formerly, it was supposed that the beneficial effects of mercury were proportionate to the degree of ptyalism, and thus, to eradicate particular affections, it was thought necessary to cause the evacuation of a given quantity of saliva. "I have heard," says Dr. Wilson Philip, "the late Dr. Monro, of Edinburgh, state the quantity of saliva which must be discharged daily, to eradicate particular affections." Modern experience has proved the incorrectness of this notion; and we now rarely find it necessary to excite a high degree of salivation; indeed, frequently it would be prejudicial, but we sometimes find it requisite to keep up this effect for several weeks, particularly in diseases of a chronic character.

Production of sore mouth and salivation.—One of the most efficacious methods of putting the system under the influence of mercury, is *friction* with the *unguentum hydrargyri;* but the troublesome and unpleasant nature of the process is a strong objection to it in practice, more especially in venereal diseases, in which our patients usually desire secrecy. In the year 1779, Mr. Clare proposed a new method of causing salivation by friction, and which consists in rubbing two or three grains of calomel, or of the protoxide, on the inner surface of the cheeks and gums. It is said that the metal quickly becomes absorbed, and causes salivation, and if care be taken not to swallow the saliva, diarrhœa does not occur. Notwithstanding that Hunter, Cruikshank, and others, have tried this plan, and reported favourably of it, and that it is free from the objections made to the use of mercurial ointment, it has never been a popular remedy. *Fumigation*, as a means of affecting the general system, is an old method of treating venereal dis-

eases. Turner employed for this purpose cinnabar, Lalouette calomel, and the late Mr. Abernethy the protoxide. Baumé used *mercurial pediluvia* to excite salivation, composed of half a grain of corrosive sublimate dissolved in a pint of distilled water, and in a solution of this strength the patient immersed his feet for the space of two hours; several objections, however, exist to the practice, which has been rarely followed. Upon the whole, the most convenient method of producing salivation is by the *internal use of mercurials*, particularly of those preparations which are mild in their local action, as blue pill, calomel, and the *hydrargyrum cum cretâ*.

Treatment before and during salivation.—Formerly the use of mercurials was preceded by antiphlogistic measures, such as blood-letting, purging, and low diet, but they are now rarely resorted to, though useful, by facilitating absorption. Occasionally great difficulty is experienced in affecting the mouth, a circumstance which may arise from the irritable condition of the bowels; and when this is the case you had better resort to inunction, or conjoin opium or vegetable astringents. Sometimes, however, the system appears insusceptible to the influence of mercury, and this may arise from idiosyncrasy, or from the presence of some disease, particularly fever. Emetics and blood-letting are useful in these cases, as they promote absorption; and as the influence of the former depends on the state of nausea produced, tartar emetic will be the best vomit, since it is the most powerful nauseant. Varying the mode of administering the mercury will also sometimes facilitate its operation on the system: thus if you have been employing it internally, try inunction, and *vice versâ*.

During the time that the patient's mouth is sore, he should, if possible, confine himself to the house, use warm clothing, avoid exposure to cold, take light but nourishing food, and regulate the state of his stomach and bowels. If the discharge become excessive, or ulceration of the gums take place, you will of course stop the further use of mercury; and, in order to moderate the effect already produced, let your patient be freely exposed to a cool but dry air, use purgatives and opium, and wash his mouth with some astringent and stimulating liquid. I have generally employed, as a gargle, a solution of the chloride of soda or of lime,—but in the absence of these, a solution of alum, or of sulphate of copper, may be used. With regard to internal remedies, I have no confidence in any as having a specific power of stopping salivation, though sulphur, nitre, iodine, and other substances, have been strongly recommended. Sometimes sulphate of quinia is administered with advantage.

Accidents during salivation.—Occasionally during salivation certain effects result from mercury which are in no way necessary or useful in a therapeutical point of view: on the contrary, some of them are highly prejudicial. Thus sometimes *excessive salivation, with ulceration of the gums*, takes place, as already noticed: not unfrequently *gastro-intestinal irritation* (or actual inflammation) comes on, and which may require the suspension of the use of mercury, or its employment by way of inunction, or its combination with opium or vegetable astringents. I have already noticed *eczema mercuriale*, *mercurial erethysm* of Pearson, and *blackening of the skin*, as other occasional effects. In feeble and irritable habits, mercury sometimes disposes sores to *slough*. Occasionally a kind of *metastasis* of the mercurial irritation is observed: thus swallowing a large quantity of cold water, or exposing the body to cold and moisture, has caused a temporary cessation of salivation, attended with violent pains, or convulsions, or great irritability of stomach.

Diseases for which salivation is employed.—Having offered these general remarks on salivation as a remedial agent, I proceed to notice its use in particular diseases.

(*a.*) *Fever.*—In the first place let us examine its efficacy in fever. It has been said that salivation diminishes the susceptibility to the contagion of fever, whether common or specific; but that it is not an absolute preventive is shown by the fact, that patients under the full influence of mercury have caught fever and died of it, as you will find noticed by my friend Dr. Clutterbuck, in his "*Inquiry into the Seat and Nature of Fever.*" I have several times used mercurials in fever (I speak now of their employment as sialogogues), and, I believe, for the most part, with advantage. I have only used them when there was some marked local determination or inflammatory condition. I have seen three fatal cases of fever in which mercurials were used profusely, without having any effect on the mouth; but in other instances in which the mouth became affected, recovery took place. Whether this was the consequence of the mercurial action, or the salivation was the result of the mitigation of the disorder, cannot be positively asserted, though I think the first more probable. The great indisposition of the system in fever to take on the mercurial action, is frequently a most annoying circumstance. It may sometimes be overcome by the employment of mercurials, both internally and exter-

nally. Mr. Lempriere, who practised in Jamaica, finding that calomel was often exhibited in immense quantities without exciting any apparent action, was induced to employ corrosive sublimate in doses of the eighth part of a grain, with the addition of ten drops of laudanum, and this quantity was repeated every hour, until some affection of the mouth was observed, or until the more alarming symptoms had considerably abated.

Before leaving the subject of fever, I ought to mention, that the beneficial influence of mercurials has been more particularly experienced in the fevers of warm climates, but more especially those of the East Indies; for it has been said by several writers, that in the yellow fever of the West Indies its beneficial effects are not very evident.

(*b.*) *Inflammation.*—Of late years various forms of inflammation have been most successfully combated by the use of mercury, sometimes where other means were of no avail. Hence this mineral is frequently called an *antiphlogistic*. We are principally indebted to Drs. Hamilton (of Lynn), Yeats, and Wright, as also to Rambach, for its use in this form of disease. It is quite impossible to explain its *modus operandi*—that is, to refer its influence to any other more general mode of operation. To say, as some have done, that mercury acts by equalizing the circulation — that is, by diminishing the quantity of blood in the inflamed part, by increasing it in other parts of the body, is a very unsatisfactory, and too mechanical a mode of explanation, and one, moreover, which is open to several objections.

It has been stated that mercury may be employed in every disease whose name ends in *itis;* but it is not equally serviceable in all. However, some difficulty is experienced in attempting to generalise; that is, to point out in what circumstances those inflammations agree which are benefitted by it. It appears, however, that the *nature of the tissue,* and the *structure of the organ affected,* as well as the *kind* of inflammation, are points of considerable importance as affecting its use.

Thus it appears that inflammations of *membranous tissues* are those principally benefitted by a mercurial plan of treatment; and more especially those in which there is a tendency to the exudation of coagulable lymph, or of serous fluid—as meningitis, pleuritis, pericarditis, and peritonitis (particularly of puerperal women). In inflammation of the lining membrane of the air-tube, but more especially in croup, or as it is sometimes termed, plastic inflammation of the larynx, mercury is one of our most valuable remedies; and as this disease is one which terminates rapidly, no time should be lost in getting a sufficient quantity of mercury into the system. Calomel is usually employed; but when the bowels are very irritable, the *hydrargyrum cum cretâ,* or even mercurial inunction, may be resorted to. In inflammation of the tunics of the eye, particularly iritis, mercury (next to blood-letting) is the only remedy on which much confidence can be placed; and we use it not merely with a view of putting a stop to the inflammatory action, but also in order to cause the absorption of the lymph already effused. In inflammation of the synovial membranes, mercury has been employed, and in some cases with manifest advantage.

The *structure of the organ* influences the effect of mercury: at least it is well known that this mineral is more beneficial in inflammation of certain organs (the liver, for example) than of others; and we refer it to some peculiarity in the structure of the part affected. In hepatitis of either temperate or tropical climates (particularly of the latter), mercury is advantageously employed: blood-letting, however, should be premised, particularly in the disease as usually met with in this country. In peripneumonia, more especially when hepatization has taken place, the best effects have sometimes resulted from its use; of course, after the employment of blood letting. In inflammation of the substance of the brain, also, this mineral may be advantageously resorted to, after the usual depletives.

The *nature* or *quality of the inflammation* also influences the effects, and thereby the uses, of mercury. Thus, in syphilitic inflammation, mercurials are of the greatest utility; less so in rheumatic inflammation; still less in scrofulous; and most decidedly objectionable in cancerous or scorbutic diseases. The treatment of rheumatism by calomel and opium has found many supporters; and, undoubtedly, when the febrile action does not run too high, or when the pericardium becomes affected, calomel, preceded by blood letting, will be found serviceable. The scrofulous habit is for the most part unfavourable to the use of mercury, given as a sialogue, but there are cases in which it is not only admissible but serviceable—as scrofulous ophthalmia, when of an acute kind. In all diseases of a malignant character, mercurials are highly objectionable.

(*c.*) *Venereal diseases.* — It was formerly the opinion of surgeons that the symptoms of venereal diseases were progressive, and never disappeared until mercury was administered; but it has, of late years, been clearly proved that this notion is erroneous: and we are indebted to some of our army surgeons—namely, to Messrs. Ferguson, Rose, Guthrie, Hennen, and

Bacot, and to Dr. Thomson—for showing that the venereal disease, in all its forms, *may* be cured without an atom of mercury. Moreover, it is fully established by the experience of almost every surgeon, that while in some instances mercury exercises a beneficial influence hardly to be observed, with respect to any other disease or any other remedy, yet, that in some cases it acts most injuriously; and it is generally supposed, that many of the bad venereal cases formerly met with, arose, in great part, from the improper use of mercury. It is a point, therefore, of considerable importance, to determine what cases are best adapted for a mercurial, and what for a non-mercurial, method of treatment; for in admitting the *possibility* of a cure without this agent, it is not to be inferred that the method is either *eligible* or *expedient*;—nay, the very persons who have proved this possibility, admit that in some cases this mineral, given so as to excite moderate salivation, is advisable. It is not, however, easy to lay down rules; and, unfortunately, practitioners are not agreed on the circumstances indicating or contra-indicating its use. Mr. Carmichael relies principally on the eruption, and, next to this, on the appearance of the primary ulcer; and, of the four forms of the venereal disease which he has described—namely, the *papular*, the *pustular*, the *phagedenic*, and the *scaly*—full courses of mercury are required, he says, in one only—namely, the scaly; in which the primary sore is the Hunterian chancre, or callous ulcer, and the eruption partakes of the characters of lepra, or psoriasis. You will find these criteria good, as general ones, but they are not absolute; for, in the first place, it has been satisfactorily proved by the experiments made in the military hospitals, that even this scaly form of the disease may get well without mercury; and, secondly, in the papular and pustular forms, you will sometimes find mercury a most valuable agent; and I have seen several cases of the papular variety which speedily got well under its use, though they had resisted other modes of treatment. Perhaps the best general rule to follow, and one sanctioned by Hennen, Rose, Guthrie, and Thomson, is, to use moderate quantities of mercury whenever the disease does not readily subside under the use of ordinary methods of treatment.

Several circumstances affect the use of mercury in this disease, and of these I may notice the following:—

(α.) *Scrofula.*—Some of the worst forms of the venereal disease that I have seen have occurred in scrofulous subjects; and it has appeared to me, that in what I may call venereo-scrofulous disease, mercury is rarely serviceable, but, on the contrary, generally prejudicial. One case which fell under my notice was that of a medical student, who, after three years suffering died, having been made much worse on two occasions by what I conceived to be the improper use of mercury: once, by his own act; and a second time, by the advice of the surgeon of his family.

(β.) *Condition of the ulcer.*—Another point deserving your attention in deciding on the use of mercury, is the condition of the primary sore: if it be much inflamed, or of an irritable nature—if it be of the kind called phagedænic, or at all disposed to slough—mercury must be most carefully avoided, as it increases the disposition to sloughing. In one case that fell under my notice, a gentleman lost his penis by the improper use of mercury, under the circumstances just mentioned.

(γ.) There are various other conditions which contra-indicate the use of mercury, such as great *debility* or *irritability of system*,—when there is *much inflammation of the throat*,—and, according to Dr. Hennen, in *affections of the bones* during the stage of periostitis.

(*d.*) *Cholera.*—Writers on the spasmodic cholera, both of this country and of India, speak for the most part favourably of the effects of mercury, especially in the form of calomel. I may refer to the works of Drs. Johnson, Venables, and Hamett, and of Messrs. Annesley, Orton, and Searle, for evidence on this point. Drs. Dickson and Rankeen, indeed, appear to regard it as a useless remedy; but I have met with no writers who attribute ill effects to it. Unfortunately those who advocate its use are not agreed as to the dose, or frequency of repetition; some advising it as a purgative; some as a sedative, in combination with opium; others, lastly, using it as a sialogogue. It is deserving, however, of especial notice, that when salivation has taken place, the patient has in general recovered; but in the worst cases this effect could not be produced. I shall have some further remarks to make on this subject when I speak of calomel.

(*e.*) *Dropsy.*—In this disease mercurials may do either good or harm. Thus when the dropsical effusion depends on inflammation, they may be employed with the best effects, as when hydrocephalus arises from meningitis, or hydrothorax from pleuritis. When ascites is occasioned by an enlarged liver, which, by causing compression on the vena portæ, gives rise to effusion, mercurials are sometimes beneficial. On the contrary, when dropsy occurs in old subjects, and when it depends on, or is accompanied by, debility of the general system, salivation is almost always hurtful. Moreover, when the effusion

arises from mechanical causes not removable by mercury, as obliteration of any of the venous trunks, or pressure of malignant tumors, salivation is hurtful. Occasionally dropsical effusion takes place without any appreciable cause, and then, of course, if mercury be employed, it must be in part on speculation.

(*f*). *In chronic diseases of the viscera*, especially those arising from or connected with inflammation, mercury is frequently serviceable. Thus, in enlargement or induration of the liver,—in hepatization of the lungs, &c. In those diseases commonly termed malignant, as cancer and fungus hæmatodes, and also in diseases of a non-malignant character, but occurring in debilitated subjects, mercurials, given so as to excite salivation, are objectionable.

(*g*.) *Chronic affections of the nervous system.*—Mercury has been recommended in paralysis, and on some occasions has proved exceedingly efficacious. I have only seen one marked case of relief, or rather, I ought to call it, complete recovery: the patient (a young man) was kept under the influence of mercury for two months, by the advice of two physicians who attended the case with me. When paralysis arises from lead, Dr. Clutterbuck has occasionally found mercury useful. In tetanus, mania, epilepsy, hysteria, tic douloureux, and other affections of the nervous system, mercurials have been used, and now and then with apparent benefit.

(*h*.) *Against parasitical animals.*—Mercurials are sometimes used to destroy parasites both of the skin and alimentary canal. I have already mentioned that they have no specific efficacy against worms.

I do not think it necessary to enter into any further details respecting the uses of mercurials generally; and I, therefore, proceed to notice the preparations of this metal individually.

MERCURIALS PREPARED BY TRITURATION.

History.—I now proceed to notice those *mercurial compounds prepared by triturating metallic mercury with another substance.* Some of these have been long in use; for Aristotle says that by mixing mercury for a long time with saliva, a remedy is formed which is useful in certain cutaneous diseases. Under this head I shall examine the following compounds:—*Hydrargyrum cum cretâ*: *hydrargyrum cum magnesiâ*; *pilula hydrargyri*; *unguentum hydrargyri*; and *emplastrum hydrargyri.*

Theory.—Chemists are not agreed as to the state or condition of the mercury in these preparations. Some consider the metal to have undergone no chemical change, but merely to have become very finely divided. Berzelius, Dumas, Guibourt, and Geiger, may be mentioned as supporters of this opinion. Others, Mr. Donovan for example, think that by trituration a small portion of the protoxide of mercury is formed, and that this is the active ingredient. Lastly, Mr. Phillips has suggested that they may contain a suboxide. One fact seems to be quite certain: the greater part, if not the whole, of the mercury is in the metallic state; and I am inclined to believe that the presence of any oxide of mercury is not essential.

1. *Hydrargyrum cum Cretâ.*

History and synonymes.—This compound (called also *mercurius alcalisatus*, or *æthiops absorbens*,) is first mentioned, I believe, by Burton, in 1738.

Preparation.—It is prepared by rubbing three ounces of mercury with five ounces of chalk, until globules are no longer visible. On account of the tediousness of the process, it is usually prepared by steam power: a cannon ball being made to revolve constantly in a large mortar containing the chalk and mercury.

Theory.—If this powder be digested in acetic acid, the lime of the chalk is dissolved, and the carbonic acid escapes; but the mercury is totally insoluble in the acid, and hence it is not the protoxide. If examined by a lens, the residuum is found to consist of minute separate globules, which readily whiten silver and gold, shewing they are in the metallic state. Hence it would appear the trituration effects no chemical change on the mercury.

Properties and characteristics.—It is a greyish powder, which effervesces on the addition of acetic acid, yielding a solution of lime, which may be distinguished by the tests for the calcareous salts already mentioned. By digestion in nitric acid, we obtain a solution known to contain mercury by the characters already mentioned for the mercurial preparations generally.

Composition.—It consists of—

Carbonate of lime	5 parts.
Finely divided metallic mercury	3 parts.
	8

Physiological effects.—This is an exceedingly mild mercurial preparation; in full doses it acts as a gentle mild laxative, and sometimes creates a little sickness. The chalk, of course, renders it antacid. By repetition, it occasions the constitutional effects of mercury already described.

Uses.—It is frequently employed as an *alterative* in children of a scrofulous habit, and in disorders of the digestive organs, in which we wish to produce a slight affection of the system with the least possible

annoyance to the alimentary canal. It is sometimes employed as a *sialogogue*, in children and in adults. Thus it is given to infants born with syphilitic eruptions.

Dose.—For an adult the dose is from five grains to a scruple, or half a drachm.

2. *Hydrargyrum cum Magnesiâ.*

Under this name there is a compound in the Dublin Pharmacopœia, prepared by rubbing mercury with manna until the globules disappear, and then washing out the manna with water, and adding subcarbonate of magnesia. Its effects and uses are analogous to the preparation just described.

3. *Pilula Hydrargyri.*

History.—The oldest formula for mercurial pills is that of Barbarossa (at one time admiral of the Turkish fleet, and afterwards governor, or king, of Algiers), and which was communicated, by him, to Francis the First, king of Franconia, who made it public. The common name for this preparation is *blue pill*, or *pilulæ cæruleæ*.

Preparation.—It is prepared by rubbing two drachms of purified mercury with three drachms of confection of roses, until globules are no longer visible, and then adding a drachm of powdered liquorice-root. The trituration is usually effected by steam power.

Theory.—By trituration, the metal is reduced to a finely-divided state, and becomes intimately mixed with the confection and liquorice powder.

Properties.—It is a soft mass, of a convenient consistence for making into pills, and has a dark blue colour. When rubbed on paper, or glass, it ought to present no globules.

Composition.—Three grains of this pill mass contain one grain of mercury. If any sulphuric acid should have been added to the confection, to brighten its colour, some subsulphate of mercury will be formed; a compound which is very energetic, and, therefore, great care should be used to obtain pure confection.

Physiological effects.—In full doses (as fifteen grains) it frequently acts as a purgative. In small doses it is alterative, and, by repetition, produces the constitutional effects of mercurials generally, and which I have already described. It may be regarded as a mild, and, at the same time, most useful preparation.

Uses.—To purge the bowels, the practice of giving a blue pill at night, and a senna draught the following morning, has become somewhat popular, in consequence of its being recommended by the late Mr. Abernethy, in various disorders of the chylopoietic viscera. As an alterative, in doses of two or three grains, it is frequently resorted to. Lastly, it is one of the best internal agents for exciting salivation, in the various diseases to which mercury is adapted.

Administration.—The usual mode of exhibiting it is in the form of pill, in the doses already mentioned; but it may also be administered when suspended in a thick mucilaginous liquid. If the object be to excite salivation, we may give five grains in the morning, and from five to ten in the evening; and to prevent purging, opium may be conjoined.

4. *Unguentum Hydrargyri.*

History and synonymes.—Mercurial ointment was known to, and employed by, the ancient Arabian physicians—for example, Abhenguefith, Rhazes, and Avicenna: so that it has been in use certainly 1000 years. However, Gilbertus Anglicus, who lived about the commencement of the thirteenth century, was the first who gave a detailed account of the method of extinguishing mercury by fatty matters. Besides its more common appellation of *mercurial ointment*, it was formerly termed *blue*, or *Neapolitan ointment*. According to the French new pharmaceutical nomenclature, its name is *Liparolé de mercure.*

Preparation.—It is prepared by rubbing one part of mercury with one part of fatty matter (lard, with a small portion of suet), until globules are no longer visible. To promote the extinction of the mercury, the metal should be previously triturated with some old mercurial ointment. Rancid lard also assists the extinction of the globules.

Theory.—Some assert that the mercury is in a finely-divided metallic state, though, if well prepared, there are no appearances of globules, when the ointment is examined by a lens. In favour of this view Guibourt states, that by digesting æther on mercurial ointment, the fatty matter may be dissolved and liquid mercury obtained, in weight equal to that used in making the ointment. Now it is unlikely, if the mercury had been previously oxidized, that the æther could deoxidize it; and therefore, this experiment, (supposing the results to be those mentioned) appears almost decisive that the mercury is in the metallic state. Mr. Donovan, however, thinks that part of the mercury attracts oxygen, and that the oxide thus formed unites with the fatty matter. I have seen no satisfactory explanation of the efficacy of old mercurial ointment in extinguishing the mercury; Guibourt offers the following:—By trituration, both lard and mercury assume

oppositely electrical states, the lard becoming negative, the mercury positive; these states, he supposes, determine a more intimate mixture of the particles, and a greater division of the mercury. Now rancid lard and old mercurial ointment, having attracted oxygen from the air, more readily take on the negative condition, and hence their efficacy in promoting the extinction of the mercurial globules. Guibourt also asserts, that mortars of marble or wood are better adapted for making this ointment than those of metal, on account of their power of conducting electricity being less.

Properties.—It is an unctuous fatty body of a bluish grey colour, and if properly prepared, gives no traces of globules when rubbed on paper, and examined by a microscope.

Composition. — In the London Pharmacopœia there are two mercurial ointments, a stronger and a weaker: the first contains 30 grains, the second 10 grains, of mercury, in every drachm.

Physiological effects.—Mercurial ointment possesses very little power of irritating the parts to which it is applied; but whether swallowed or rubbed into the integuments, readily produces the constitutional effects of mercury. Thus Cullerier says, that three or four pills, containing each two grains of this ointment, and taken successively, have often sufficed to excite violent salivation. He also states, that if the object be to produce salivation, in a very short space of time we may effect it by giving half a drachm of the ointment in the space of 24 hours.

When rubbed into the surface of the body, it produces the same constitutional effects as the other preparations of mercury; but if the lard which it contains be not rancid, no obvious local effect is usually produced. Applied to ulcerated surfaces, mercurial ointment is a stimulant, and in syphilitic sores is oftentimes a very useful and beneficial application.

Uses.—It is rarely or never administered *internally* in this country, and yet I could quote a number of good continental authorities who speak of its advantages in the highest terms. It certainly well deserves a trial where the system appears insusceptible to the influence of mercury; for Cullerier says, the difficulty with him has been rather to check than to excite salivation by it.

Applied *externally*, it is employed either as a local or constitutional remedy. Thus as a *local* agent it is used as a dressing to syphilitic sores, or rubbed into tumors of various kinds, (not those of a malignant nature, as cancer and fungus hæmatodes), with the view of exciting the action of the lymphatic vessels. Sometimes, also, it is employed to destroy parasites on the skin. As a *means of affecting the constitution* we use mercurial inunctions in syphilis; in inflammatory diseases, and, in fact, in all the cases (already noticed) in which our object is to set up the mercurial action in the system, more especially when the irritable condition of the digestive organs offers an objection to the internal employment of mercurials. It may be laid down as a general rule, that mercury may be used with more safety by the skin than by the stomach; but reasons of convenience, which I have already alluded to, frequently lead us to its internal use.

Administration.—Internally, it is given in doses of from two to five grains, made into pills, with either soap or some mild powder, as liquorice. Externally, when the object is to excite very speedy salivation, half a drachm may be rubbed into the skin every hour, washing the part after each application, and varying the seat of application. If, however, it be not desirable or necessary to produce a very speedy effect, half a drachm or a drachm rubbed in night and morning, will be sufficient. In making use of mercurial frictions, it is to be recollected they ought not to be violent, but long continued, and had better be carried on near a fire, in order to promote the liquefaction and consequent absorption of the ointment. In syphilis, and other diseases in which our sole object is the constitutional affection, it matters little to what part of the body the ointment is applied, provided the cuticle be thin (for this inorganic layer offers an impediment to absorption in proportion to its thickness). The internal parts of the thighs are usually, therefore, selected. However, in liver complaints, the inunctions are usually made in the region of the organ affected. The occasional use of the warm bath promotes the action and absorption of the mercury when the ointment is applied to the skin.

Linimentum Hydrargyri.—This is prepared by mixing mercurial ointment with lard, camphor, and solution of ammonia. It is used (by way of friction) in chronic tumors, chronic affections of the joints, &c., where the object is to excite the action of the lymphatic vessels. It is usually stated in books, that it more readily causes salivation than the common mercurial ointment, and which Dr. Paris attributes to the stimulating properties of the camphor and ammonia; but though I have frequently used it, I have never seen evidence of the truth of this statement.

5. *Emplastrum Hydrargyri.*

In the London Pharmacopœia, this is ordered to be prepared by rubbing three ounces of mercury with a fluid drachm of sulphuretted oil until the globules are no longer visible, and adding a pound of melted lead plaster. In this process, the sulphur of the sulphuretted oil forms with the mercury a sulphuret, while the remainder of the metal is mechanically divided. Each drachm of the plaster contains fifteen grains of mercury.

It is supposed to stimulate the lymphatic vessels of the parts to which it is applied, and is used as a discutient in glandular enlargements and other swellings, whether venereal or otherwise, and also to the region of the liver in hepatic complaints. Dr. Wilson Philip has seen it induce salivation.

Emplastrum ammoniaci cum hydrargyro.—This is prepared in a similar manner to the last preparation, except that the gum-resin ammoniacum is substituted for the lead plaster. It is a more powerful compound than the last, and is employed in the same cases, especially in venereal buboes.

OXIDES OF MERCURY.

1. *Protoxide of Mercury—Hydrargyri cinereum oxydum* (Ph. L.)

The synonymes for the protoxide of mercury are—*suboxide, grey, black,* or *ash-coloured oxide.*

Preparation.—In the London Pharmacopœia it is prepared by adding one ounce of calomel to a gallon of lime water, washing the precipitate which is produced, and drying it. A weak solution of potash may be substituted, with advantage, for the lime water.

Theory.—Calomel is the protochloride of mercury,—lime is an oxide of calcium. When these two compounds come in contact, double decomposition takes place: chloride of calcium is formed in solution, while protoxide of mercury precipitates.

Reagents.	Results.
$\dot{Ca}$	Ca Chl
Hg Chl	$\dot{Hg}$

The protoxide of mercury is usually mixed with some undecomposed calomel.

Properties.—Pure protoxide of mercury is black, or nearly so. The present preparation, however, is frequently greyish, owing to the presence of some undecomposed calomel. It is readily decomposed by light (especially by the solar rays), being resolved into metallic mercury and the peroxide, and becoming of an olive colour. It is odourless and tasteless.

Composition.—The officinal preparation varies in its composition. It consists essentially of the *protoxide of mercury,* but frequently mixed with varying quantities of *metallic mercury, peroxide,* and *protochloride.*

Protoxide of mercury consists of—

	Berzelius.		*Thomson.*		*Turner.*	
Mercury......	2 atoms	= 202·86	2 atoms	= 200	1 atom	= 202
Oxygen......	1 atom	= 8·01	1 atom	= 8	1 atom	= 8
		210·87		208		210

Physiological effects.—Pure protoxide of mercury is one of the least irritating of the mercurial preparations, and, therefore, when swallowed, does not produce much disorder of the alimentary canal. When taken in repeated doses, its constitutional effects are similar to those of mercurials generally.

Uses.—Mr. Abernethy employed it as a fumigating agent. The following are his directions for using it:—place the patient in a vapour bath, in a complete suit of under-garments, with a cloth around his chin. Two drachms of the oxide are then put on a heated iron within the machine in which the patient is sitting. After continuing in the bath for about fifteen or twenty minutes, the body is found to be covered with a whitish powder. The patient should be put to bed, and lie in the same clothes till morning, and then go into a tepid bath. By this mode of proceeding, Mr. Abernethy says he has known salivation induced in forty-eight hours.

Protoxide of mercury is rarely employed as an internal remedy; indeed, its varying composition is a strong objection to its use. When exhibited, it may be given in doses of from one to four or five grains. As an external application, it has been used in the form of *ointment,* and also suspended in a weak solution of chloride of calcium, under the name of *black wash.*

Ointment of the protoxide of mercury.—This is prepared by mixing one part of the protoxide with three parts of lard; and is intended to be a substitute (of a fixed strength) for the common mercurial ointment. According to Mr. Donovan, this ointment should be kept at a temperature

of 350° F. for the space of two hours, in order that the oxide and fatty matter may enter into union.

Black wash, called also *Lotio nigra*, *Aqua mercurialis nigra*, and *Aqua phagedenica mitis*, is prepared by adding calomel to lime water. The proportions of the ingredients may be varied, but in general they are one drachm of calomel to a pint of lime water. In consequence of the double decomposition which takes place between the calomel and the lime, protoxide of mercury and chloride of calcium are formed: the first precipitates, the second remains in solution. As the efficacy of the wash depends principally, if not wholly, on the oxide, the bottle must be well shaken every time previously to using it. It is a favourite application to venereal sores of almost all kinds,—in most being serviceable, in few being hurtful.

2. *Peroxide of Mercury.*

There are two preparations of this in the Pharmacopœia,—namely, *hydrargyri oxydum rubrum*, and the *hydrargyri nitrico-oxydum*.

(*a.*) *Hydrargyri Oxydum Rubrum.*

History and synonymes.—Geber gives a good account of the method of making this substance, and of the failure of his predecessors, whose errors he points out. He regards it as *coagulated mercury*. It has had other appellations, such as *hydrargyrum calcinatum*, and *mercurius præcipitatus per se*.

Preparation.—It is prepared by exposing mercury to a prolonged heat of about 600° in a tall glass vessel with a narrow mouth and broad bottom. The process is a very tedious one, occupying several weeks,—so that Geber's remark was correct, that "it is a most difficult and laborious work, even with the profoundness of clear-sighted industry." The apparatus which Mr. Boyle contrived for the manufacture of it was long termed "*Boyle's Hell*," from a notion that the mercury was tortured in it.

Theory.—The heat vaporises the mercury, which in this state attracts oxygen from the air, and forms this red or peroxide. The long neck of the vessel prevents the escape of the vapours or newly-formed oxide.

Properties.—It consists of small crystalline red scales or grains, which are odourless, but have an acrid metallic taste. It is slightly soluble in water. When heated, it first deepens in colour, and, by an increase of heat, is decomposed into mercury and oxygen. It is soluble in hydrochloric acid, forming corrosive sublimate.

Composition.—Peroxide of mercury consists of—

	Berzelius.	*Thomson.*	*Turner.*
Mercury......	1 atom = 101·43	1 atom = 100	1 atom = 202
Oxygen......	1 atom = 8·01	1 atom = 8	2 atoms = 16
	109·44	108	218

The *effects*, *uses*, and *administration*, are similar to the preparation which I have next to examine. Its dose is from half a grain to two grains.

(*b.*) *Hydrargyri Nitrico Oxydum.*

History and synonymes.—This preparation is said to have been known to Raymond Lully, in the latter part of the 13th century. It is commonly termed *red precipitated mercury*, or, for shortness, merely *red precipitate*.

Preparation.—It is prepared by dissolving mercury in diluted nitric acid, and evaporating the solution to dryness. The residuum is then to be heated in a shallow vessel until red vapours are no longer given out. The latter part of the preparation requires some little nicety, in order that the product may have a shining scaly appearance. In one chemical manufactory, in which I saw the process going on, the "shallow vessel," before alluded to, was nothing but a common earthenware dish (commonly termed a *pie-dish*), and which was placed in a sand bath, and had another dish of the same size and shape inverted over it.

Theory.—Part of the nitric acid oxidizes the mercury;—binoxide of nitrogen escapes—and the peroxide of mercury which is generated, unites with some undecomposed nitric acid, to form the bipernitrate.

Re-agents.	Results.
$3\ Hg$	$2\ \ddot{N}$
$8\ \overset{\therefore\cdot\cdot}{N}$	$3\ \ddot{H}g\ 6\ \overset{\therefore\cdot\cdot}{N}$

When this bipernitrate of mercury is exposed to heat, the nitric acid is for the most part given out, and peroxide of mercury left behind.

Properties.—It occurs in bright red crystalline grains, which are slightly soluble in water; Dr. Barker says, that 1000 parts of boiling-water did not take up more than 0·62 of this oxide. The other properties of this oxide are the same as those of the last preparation.

Composition.—As already mentioned, it consists principally of peroxide of mercury. Mr. Brande states, that 100 lbs. of

mercury yielded, at Apothecaries' Hall, 112 lbs. of this nitric oxide of mercury. This would shew that about four pounds of nitric acid are not driven off. It is to this acid, which must be in combination with some oxide, that the nitric oxide of mercury is supposed to owe its scarlet colour.

Adulteration.—Oxide of lead is the only probable adulteration: this might be readily detected by heating the suspected compound before the blow-pipe on charcoal, when a globule of metallic lead will be left behind, whereas the whole of the mercury will be volatilized.

Physiological effects.—Peroxide of mercury is an energetic local irritant, though perhaps somewhat less powerful than corrosive sublimate. When swallowed *in large doses*, it produces inflammation of the stomach and bowels, manifested by nausea, vomiting, purging, and the usual appearances after death. Whether applied externally, or taken internally, it gives rise to the constitutional effects of mercurials, which I have already described. Jacobs mentions a case in which death resulted from applying it to a wart on the face; and Fabricius Hildanus, Bartholinus, and Longius, have also reported cases in which the external use of this agent gave rise to the constitutional effects of mercury. Frederic Hoffmann, Plouequet, Girtanner, and more recently Mr. Brett*, have related instances of poisoning by its internal administration. In *small doses* (as from an eighth to a quarter of a grain, in the form of pills,) it may be taken to excite salivation, though the practice is objectionable where an irritable condition of bowels exists.

The *nitric oxide of mercury* may be considered as having a more powerful local action than the *hydrargyri oxydum rubrum* of the Pharmacopœia, on account of its containing a small portion of the pernitrate of mercury.

Uses.—It is principally employed as an *external* agent. Thus it is used as a caustic to destroy spongy excrescences, venereal warts, &c.; as a stimulant to foul indolent ulcers, whether syphilitic or otherwise, and to the eyelids in chronic inflammation of these parts. Internally, it has been principally employed in syphilis. It is employed either in the form of a finely-divided powder, or as ointment.

Unguentum hydrargyri nitrico-oxydi, or *red precipitate ointment.*—According to the London Pharmacopœia, this is prepared by adding an ounce of finely-powdered nitric oxide of mercury to a mixture of two ounces of white wax, and six ounces of prepared lard. By keeping, it undergoes change of colour, from red to grey, most likely from its partial deoxidation. Dr. Duncan says, that if it be mixed with any ointment containing resin, it quickly becomes black. This also, I presume, arises from the same cause as the last. It is a very common application to indolent sores and ulcers, in which we want to increase the discharge and improve its quality. It is employed also as an application in inflammation of the eye-lids.

Lotio (seu *aqua*) *phagedenica*—*Yellow wash.*—This is prepared by adding corrosive sublimate (from 15 to 30 grains) to a pint of lime water. Double decomposition takes place, chloride of calcium is formed in solution, and peroxide of mercury precipitates. If the quantity of corrosive sublimate be large in proportion to the lime-water, some oxichloruret of mercury will also precipitate. This wash has been long in use as an application to foul venereal ulcers.

Unguentum Hydrargyri Nitratis.

Preparation.—This ointment (frequently termed *citrine ointment*) is prepared by dissolving mercury in nitric acid, and adding the solution thus obtained to a mixture of lard and olive oil. The proportions of the ingredients directed in the London Pharmacopœia are not these which yield the the best preparation. In the following table, I have placed, side by side, the quantities directed in the London Pharmacopœia, those recommended by Guibourt, and those employed by Dr. Duncan, of Edinburgh:

	Pharmacopœia.	*Guibourt.*	*Duncan.*
Mercury	1 oz.	1 oz.	1 oz.
Nitric acid	1 oz. 3 drs.	2 oz.	3 oz. (Nitrous acid).
Lard	6 oz.	8 oz.	3 oz. 6 drs.
Oil	4 oz.	8 oz.	9 oz. 1 dr.

Theory.—When the mercury and nitric acid are mixed, the former abstracts oxygen from the latter, and forms two oxides (the proto- and peroxide of mercury), while binoxide of nitrogen is generated, part of which escapes in a gaseous state, while part reacting on some of the free nitric acid, produces nitrous acid, which gives the liquid a greenish tinge. The solution thus obtained contains free *nitric* and *nitrous acids*, and the *nitrate* and *hyponitrite of mercury.*

When this solution is added to the lard and olive oil, the free nitrous acid (or perhaps the hyponitrous acid which it contains) converts the olive oil into a solid fatty body called *elaïdine* (from ελαΐς—ελαΐδος, an olive-tree); the stearine and

* MEDICAL GAZETTE, vol. xiii.

elain of the lard also acquire a greater consistence from undergoing an analogous change. Boudet is of opinion that these changes are effected by the physical influence merely of the nitrous acid, since the decomposition of this acid is not essential to the formation of the elaïdine. The hyponitrous acid contained in the hyponitrite of mercury is capable of producing the same effect. The fatty bodies exercise a deoxidizing influence on the acids (free or combined) of the solution, and which is supposed to be independent of the formation of elaidine; and, in consequence of this, nitrogen or nitrous gas is given out. They also deoxidize the oxides of mercury, reducing the peroxide to the state of protoxide, and, by keeping, even converting the protoxide into metallic mercury; which, being in a finely-divided state, gives to the mass a greyish colour. This latter change is proved by two facts—first, the change of colour which the ointment undergoes; and secondly, if we digest æther on old citrine ointment, the fatty matters are dissolved, leaving behind metallic mercury. It is to prevent this change, that more acid ought to be employed than is directed in the Pharmacopœia.

Elaïdine is a fatty substance, distinguished from stearine in having a higher fusing point, and also in yielding a peculiar acid (termed *elaïdic*), and glycerine, when treated with caustic alkalies; whereas stearine, by saponification, yields glycerine and stearic acid. Elaïdic is distinguished from stearic acid by its less fusibility, and its greater solubility in alcohol.

Properties.—When properly prepared, this ointment has a fine yellow colour, and a soft consistence. By keeping, it is very apt to become hard; in some cases it becomes so much so, that we may readily reduce it to powder. Increasing the quantity of oil originally employed in its manufacture, checks this tendency. This ointment is very apt to become grey when mixed with other ointments, in consequence of their deoxidizing powers.

Physiological effects. — It is an irritant, and even a slight caustic. When it has undergone decomposition, by keeping, it irritates ulcers exceedingly, and even excites slight erysipelatous inflammation.

Uses.—We employ it as a stimulant and alterative in *chronic diseases of the skin*,—more particularly those affecting the hairy scalp, as the different forms of porrigo, in which it is exceedingly efficacious. It is also used as a *dressing to ulcers*—to stimulate and cleanse them—as in foul syphilitic sores and phagedænic ulcers. Lastly, it is employed in *ophthalmic diseases*,—more particularly ophthalmia tarsi, or psorophthalmia,—in which it is applied (mixed with its own weight of almond oil) by means of a camel's-hair pencil to the lids — frequently with such advantage that some have denominated it a specific in this complaint.

PATHOLOGICAL

OBSERVATIONS ON THE BLOOD:

BEING

THE CROONIAN LECTURES

Delivered at the Royal College of Physicians, May 1836,

BY GEORGE BURROWS, M.D.

Late Fellow of Caius College, Cambridge; Assistant Physician to St. Bartholomew's Hospital.

LECTURE I.

IN the former course of lectures, I commenced an explanation of the changes which take place in the blood when its circulation is arrested in the living body. This subject was divided into two parts—

1. *Description of the changes which take place in the blood when its circulation is stopped within the heart, and the proper vessels of the circulation.*

2. *Description of the changes which take place in the blood when extravasated.*

Of the first division I treated very fully, and there remains to be discussed but two of its subdivisions—viz. the changes of the blood when stagnant in the capillaries, and when stagnant in venous cells, as in the spleen.

Of the second division I only described the changes taking place in blood effused from divided vessels, or when poured out upon membranous surfaces. There remains for me to describe, of this second part—

1. *The changes which take place in blood extravasated during inflammation.*

2. *The changes taking place in blood effused into the substance of organs, in consequence of obstructions to the circulation through them.*

And, lastly, the changes occurring in blood extravasated from violence, and from altered conditions of that fluid itself.

The changes which take place in the blood when it becomes stagnant in the capillary vessels of a part, are so intimately connected with the changes which take place in the blood effused from those vessels into the tissues (and particularly when suffering from inflammation), that it will be much more convenient and intelligible to undertake the description of these two subdivisions of the subject conjointly, and

this will form the substance of the first lecture.

I shall next consider the various conditions of the blood when stagnant in the interior of organs, as in the venous cells of the spleen, or when effused into the substance of other organs, as the brain, lungs, liver, &c.

I shall conclude the subject by describing the changes taking place in blood extravasated by violence, and from altered conditions of the fluid itself; together with some general observations upon the nature of these varied changes taking place in stagnant blood in different parts of the living body.

Since the composition of my former courses of lectures on the pathology of the blood, great additions have been made to our knowledge on this interesting subject. The occasional organization of masses of fibrin within the vessels of the circulation has been admitted by more able pathologists than myself; the transformation of the blood into pus and other substances, hitherto considered the products of peculiar morbid actions of vessels, has likewise been maintained and amply illustrated; lastly, the chemical composition of the blood, in many diseases, has been investigated; the presence of principles foreign to the blood in health, has been detected; and the absence, or great diminution of its healthy constituents, has likewise been ascertained.

New facts have also presented themselves to myself during the past year, confirmatory of opinions advanced in the last course of lectures; and to a few of these I must direct attention, before I proceed to the immediate subject of the lecture.

In that storehouse of valuable pathological observations, the "*Précis d'Anatomie Pathologique*" of Professor Andral, there is a note upon the vitality and occasional organization of the blood, which I cannot refrain from quoting in his own words, because it strictly bears upon doctrines maintained in these lectures.

"The meaning of this word, organization," writes Andral, "is far from being settled, and we must not believe that the manifestation of life only occurs where there is an organization such as we find it in the higher orders of animals, such as we are therefore in the habit of representing it in our own minds, and such as we conceive it to be in all cases. If we trace the series of living beings, we observe the organs or instruments of vital acts diminish more and more, both in number and complexity; we see that they even entirely disappear, and still there will be life. Life is not the less certain in the vegetable seed, or in the drop of liquid, the primary rudiment of the embryo; yet in these corpuscles we can trace still less than in the blood the rudiments of what we commonly call organization.

"In the absence, then, of forms to which common opinion affixes the idea of life, vital acts may be accomplished. We should be far from imposing certain conditions in the arrangements of matter as necessary to the manifestation of life.

"Observation compels us to admit, that in a thousand instances life is made manifest to us, not by forms (or organization), but by acts."

These remarks of Andral upon organization must be kept constantly in mind when we are examining the transitions of a mass of coagulated fibrin from a concrete homogeneous mass into some new product, which eliminates within itself both vessels and morbid secretions.

It is perfectly true, that if the blood be regarded as a mass moving through the larger vessels, and be compared with any organized tissue, or with the parenchyma of any organ, there is no doubt a great difference between the physical qualities of the living fluid and solid. This dissimilarity, however, no longer exists, when a comparison is made between the blood in the capillaries of an organ, and the surrounding structure which it nourishes and forms; in this part of each organ the blood and the tissue are intimately blended together. In every structure there is a point where the blood must be regarded as becoming extravasated—where it mingles and combines with, and renovates the surrounding tissue—where, in fact, it becomes organized, and where its vitality is no longer a matter of doubt.

Andral, Carswell, and other modern pathologists, have pointed out that it is not only under the foregoing ordinary circumstances that a power of organization is recognized in the blood: a frequent source of its organization is often observed whenever the fibrinous part of the blood becomes coagulated, both within the vessels of the circulation, and also when extravasated. The proofs of organization within these masses of fibrin are sometimes obscure; at other times they are more manifest. A circulation is established through them; numerous and dissimilar secretions are eliminated within them; vessels are traced in their substance; the natural tissues and morbid structures are developed within them, or, perhaps, they are wholly converted into such substances.

These changes and proofs of organization in the coagulated fibrin have been strongly insisted upon in an interesting and useful work recently published by Dr. Southwood Smith, entitled "Philosophy of Health."

"The vitality of the blood is proved by

the process of organization," writes this author. "We can trace only a few steps of this process, but these are sufficient to establish the point in question. Blood effused from living vessels into the substance, or upon the surface of living organs, solidifies, without losing vitality. If a clot of blood be examined some time after it has thus become solid, it is found to abound with blood-vessels. Some of these vessels are obviously derived from the surrounding living parts. The minute vessels of these parts, as can be distinctly traced, elongate, and shoot into the clot. The clot thus acquires blood-vessels of its own. By degrees a complete circulation is established within it. The blood-vessels of the clot act upon the blood they receive just as the vessels of any other part act upon their blood,—that is, transform it into the animal matter it is their office to elaborate.

"In this manner a clot of blood is converted into a component part of the body, and acquires the power of exercising its own peculiar and appropriate functions in the economy.

"But while, in this process, some of the vessels of the clot can be distinctly traced from the surrounding living parts, others appear to have no connexion with those parts; at all events, no such communication can be traced. These vessels, the origin of which cannot be found external to the clot, are supposed by some physiologists to be formed within it. Within the living egg, during incubation, certain motions or actions are observed spontaneously to arise, which terminate in the development of the chick. Analogous motions arising within the clot, terminate, it is conceived, in the development of blood-vessels. According to this view, a simultaneous action takes place in the clot and the living part with which it is in contact; each shooting out vessels, which elongate, approximate, unite, and thus establish a direct vital communication. Whether this view of the process of organization be the correct one or not, does not affect the present argument. It is certain that a clot of blood, surrounded by living parts, becomes organized; it is certain that no dead substance, surrounded by living parts, becomes organized; it follows that the blood possesses life *."

The same author has maintained this doctrine of the organization of the fibrin of the blood in another † publication, with strong arguments, supported by the well-known observations of John Hunter.

In Dr. Carswell's work on the *Elementary Forms of Disease*, in his fasciculus on *Mortification*, that kind of mortification which has been called gangræna senilis is very correctly described as depending upon ossification of the coats, or actual obliteration of the arteries of the part. Several cases of this kind which I have had the opportunity of examining after death, evidently depended upon these conditions of the arteries, and not upon any inflammation of the lining membrane of the vessels. Upon this point of pathology, Dr. Carswell writes thus strongly:—

"Leaving aside the incontrovertible evidence of the material facts which demonstrate the truth of the position (that this form of mortification is the immediate consequence of a deficient supply of arterial blood from a mere mechanical obstacle to the circulation of this fluid), there are other circumstances which shew that inflammation of the arteries cannot be the cause of gangræna senilis. In the first place, the obstructing causes, viz. fibrous, fibro-cartilaginous, and osseous tissue, could not owe their origin to inflammation in a space of time so short as that which often marks the duration of this disease; and in the second place, the presence of these accidental tissues in the arteries is no proof that inflammation had ever existed in these vessels.

"Stagnation of the blood from mechanical or physical causes, is sufficient to give rise to the formation of these tissues by means of the fibrin of this fluid."

Dr. Carswell thus admits that the fibrin of the coagulated blood within the vessels may become organized, and may be converted into fibrous, fibro-cartilaginous, and osseous tissue, without the previous intervention of inflammation of the lining membrane of the arteries.

Some of our own most distinguished anatomists of the present day deny the organization of these masses of fibrin. It appears to me that this denial arises partly from the remains of the exclusive dominion which morbid anatomy so long held over men's minds in the contemplation of disease, and partly because the constant occupation of these eminent men in the dissecting-room has led them to regard a structure as organized only when the vessels of its circulation can be detected by the minute scrutiny of their scalpel, or made manifest to the eye by a successful application of the injecting syringe. The physiologist or pathologist is, however, induced, by evidence no less conclusive, to admit the organization of a natural tissue or morbid structure, when the anatomist has failed to demonstrate the vessels of its circulation.

How large a number of beings would be excluded from the class of organized creatures if such a proof of circulation

* Philosophy of Health, vol. i. p. 352.
† Penny Cyclopædia; art. *Blood.*

through them were required before they were acknowledged to be organized.

To put this part of my argument in a clearer and more forcible manner, I will borrow some observations on the nature and variety of circulation from a distinguished member of this College, and author of the Bridgwater Treatise *on Animal and Vegetable Physiology*. Dr. Roget expresses himself in the following language (vol. ii. p. 231):—

"A comprehensive survey of the different classes of animals, with reference to this function of circulation, enables us to discern the existence of a regular gradation of organs, increasing in complexity as we ascend from the lower to the higher orders; and showing that here, as in other departments of the economy of nature, no change is made abruptly, but always by slow and successive steps. In the very lowest tribes of zoophytes, the modes by which nutrition is accomplished can scarcely be perceived to differ from those adopted in the vegetable kingdom, where the nutritive fluids, instead of being confined in vessels, appear to permeate the cellular tissue, and thus immediately supply the solids with the materials they require; for in the simpler kinds of polypi, of infusoria, of medusa, and of entozoa, the nourishment which has been prepared by the digestive cavities is apparently imbibed by the solids, after having transuded through the sides of these organs, and without being previously collected into other and more general cavities. This mode of nutrition, suited only to the torpid and half vegetative nature of zoophytes, has been denominated nourishment by imbibition, in contradistinction to that by circulation; a term which implies not merely a system of canals such as those existing in the medusæ, where there is no evidence of the fluids really circulating, but an arrangement of ramified vessels composed of membranous coats, through which the nutrient fluid moves in continued circuit.

"In some of the minuter species of crustacea, the fluids have been seen, by the aid of the microscope, moving within the cavities of the body, as if by a spontaneous impulse, without the aid of a propelling organ, and apparently without being confined in membranous channels or tubes of any sort. This kind of diffused circulation is also seen in the embryos of various animals, at the earliest periods of their development, and before any vessels are formed."—(Page 235.)

This is the kind of circulation we must expect to find traces of in the early development of organization in coagulated masses of fibrin within the living body. If the embryo passes rapidly through successive gradations of ascending complexity of organization, from the mere vesicle to its more perfect and complete organization, so does the living blood not unfrequently afford examples of analogous transformations in the living body.

Many distinguished anatomists, however, have denied this occasional organization of masses of fibrin within the living body; and very recently, Dr. Benjamin Babington, in adverting to my Pathological Observations on the Blood, delivered in the Croonian Lectures of 1835, has thus expressed himself, in the new Cyclopædia of Anatomy (art. *Blood*):—

"I can imagine nothing more unlikely than that an insulated mass of fibrin, owing its origin to the mere coagulation of the blood from rest, and therefore only by gravitation brought in contact with the sides of the vessel which may contain it, should assume an organized structure.

"I have looked carefully for unequivocal signs of vitality in these false polypi, and I confess that I have never been able to satisfy myself of its existence."

On the other hand, it appears to myself, that as the blood is deposited in detail by the nutrient arteries of tissues, and there becomes an integral part of the structure, lives and assists in accomplishing vital functions, so is it far from unlikely that such blood, when deposited in masses, should become organized and exhibit changes which are the undoubted effects of vital actions. Opportunities certainly do not very often occur for observing such phenomena, but I have had several, and the following facts are worthy of recital:—

Mr. Bayntin, the curator of the museum at St. Bartholomew's Hospital, was present, not long since, at the slaughtering of a horse, for the purpose of obtaining some parts for anatomical demonstration. He removed from the pubic and inguinal regions some hard masses, which at that time appeared to him to be enlarged absorbent glands; but upon subsequent careful examination, with Mr. Stanley and myself, it was discovered that these masses were coagula of blood in the veins. The lining of the veins in contact with these coagula was perfectly smooth, pale, shining, and apparently healthy.

Two of these coagula were about the size and shape of filberts; the others were smaller. One of the larger, upon being divided, exhibited a number of concentric layers of firm fibrin, with the colouring matter of the blood in it, very similar to the coagulum of an aneurismal sac. This mass of fibrin was contained in a firm elastic capsule, which could be peeled off with facility. The division of another of these masses exhibited the same internal appearance as the former, and it was contained in a similar dense elastic capsule. Upon

stripping off this outer capsule, there appeared a second membrane investing the contained coagulum; and small plates of osseous matter were distinctly perceptible in this second investing membrane.

A third coagulum, of nearly the same size and external appearance, was likewise found. This had strong attachments at two points to the lining of the vein, by means of fibrous cords. This third coagulum was connected by a long, firm, cylindrical, fibrous band, to a fourth coagulum, of the same nature as the others, but rather smaller. A perfectly healthy valve covered the proximal or cardiac end of this last-mentioned coagulum. The preparation of these parts is preserved in the museum of St. Bartholomew's Hospital.

I have recently learnt that such coagula are not uncommon in the veins of horses, and that they are also found in the pulmonary veins of some amphibious animals. When we consider the great obstruction to circulation through the lungs during the periods of submersion of such amphibia, it is not surprising that coagula should be found at any part of the pulmonary circulation. The varied condition of these masses of coagulated blood in the veins of this horse, appear to me to offer some striking elucidations of the changes which coagulated blood is capable of undergoing within the vessels, and likewise strong corroboration of the opinions I have advanced in this College, in the Croonian Lectures of 1835.

In the first place, the blood appears to have coagulated in successive layers, and to have retained its colouring matter, as it does in the coagula of aneurismal sacs. Each of these coagula was surrounded by a distinct membranous capsule; others possessed a second investing capsule, in which was deposited distinct plates of ossific matter: these, to my mind, are indisputable proofs of the effects of organization accomplished within and around these coagula. Other coagula were attached to the lining membrane of the vein by fibrous cords, and these latter would afford a ready means by which their organization would be accomplished. The fibrous band connecting two of these coagula together, appeared to be nothing but a continuation of the same coagulum through the vein, but which had shrunk, and had thus been gradually changed into a cylindrical cord.

Although two of these coagula apparently had no connexion with the lining of the vein, it is probable that some slight fibrous connexions were accidentally ruptured on removing them. I am, then, of opinion that these fibrous bands, connecting the coagula with each other, and with the lining of the vein, were primarily nothing more than portions of coagula loose in the vein, and which, upon coming in contact with its lining, had excited increased vascularity there, and from that source had gradually been accomplished the organization of the clots. This process of organization has been ably illustrated by Mr. Hunter, and explained upon the principle which he terms contiguous sympathy; that is, when two living parts are brought into contact in the living body, union between the two is the result. I regret that I have not other preparations to illustrate these opinions, but all who are conversant with minute morbid anatomy are aware that it often happens, after thoroughly examining morbid structures, that the parts are no longer in a condition to be demonstrated to others, or to be preserved in the form of a preparation.

I shall now proceed briefly to consider *what are the changes which take place in the blood when its circulation is arrested in the capillaries, or when extravasated from them, and more particularly during that series of morbid phenomena, the sum of which is usually termed inflammation.*

If we refer to the extensive series of experiments performed by Dr. Wilson Philip, and Dr. Charles Hastings, to illustrate the changes taking place in the blood-vessels during inflammation, (and these experiments have been recently repeated, and their results confirmed by M. Gendrin and Dr. Carswell) it appears that there is a stage in inflammation when the circulation of the blood is slackened and almost stagnant in the dilated capillaries.

From this stagnation, according to Gendrin and Hastings, there results a modification of the globules of the blood; they gradually change their colour, and from the divided capillaries of the inflamed part there exudes a purulent fluid. Gendrin affirms that when inflammation has been induced in the web of a frog's foot by the application of various stimulants, that it is easy to watch the progress of suppuration at the edge of a wound made in the web. If a highly polished lancet be passed beneath an excessively thin layer of membrane at the edge of the wound, it offers a convenient method of examining the state of this layer: the blood is observed to slacken its course within the dilated capillaries of the inflamed part, and as it approaches towards the centre of the inflammation, the globules of blood lose their colour, and are changed into globules of pus. The blood thus altered, then exudes very slowly from the edge of the wound, in the form of pus.

In Dr. Hastings's experiments the retarded circulation in the capillary vessels of an inflamed part was always accompa-

nied with an alteration in the appearance of the blood. In the natural state of this fluid, globules could be distinctly seen, but after the inflammation had commenced, the globular arrangement disappeared, the blood became redder in the part, and the most minute capillaries were distended with it. Dr. Hastings then proceeds to describe the remainder of the phenomena in the following words, (P. 92, *On Inflammation*):—" If, however, the inflammation proceed, the blood becomes nearly stagnant; it continues very red, and the vessels are much dilated. The blood then ceases to move in the dilated vessels, it loses its red colour, and becomes of a yellowish brown hue. When this high degree of inflammation is not relieved, sphacelus ensues. The part then feels softer to the finger, and gives way with less force. The separation of the dead from the living part takes place soon after this change in the colour of the blood."

Dr. Hastings has in this passage described the transformation of blood in the capillaries into pus, although it was not written with such intention.

Dr. Carswell also states, (*Elementary Forms of Disease* — Fasciculus *Pus*,) " that from the very obvious character of the facts elicited by microscopical observations upon the capillary vessels of the transparent parts of animals in a state of inflammation, no doubt can be left in the mind that the formation of pus is a consequence of a modification of the blood, manifested more especially by a change taking place in the colour, transparency, and bulk of the globules of this fluid, after its circulation has been arrested in the capillary vessels during inflammation; that this change in the globules takes place in the capillary vessels, and that these vessels conduct the globules in this state to the exterior, where they appear combined with the serum of the blood, under a peculiar liquid form, or that which we call pus. Such is one mode in which pus is formed, and which has been compared to the process of secretion."

Admitting the accuracy of the observations of Hastings, Gendrin, Dr. Carswell, and others, it would appear that pus is formed from the blood, or the latter fluid is convertible into the former, without the previous organization " of a new or peculiar structure of vessels, or a new disposition and mode of action of the old," which Mr. Hunter thought to be necessary, and which led him to consider pus as a glandular secretion. A similar change in the blood takes place, when it is poured forth into the cellular tissue, as it often is in violent inflammations.

M. Gendrin, in that excellent and most elaborate work, the " Histoire des Inflammations," has clearly pointed out that in every case of violent inflammation of the cellular tissue, the increase of bulk and induration of the part are in consequence of the presence of effused coagulable lymph and extravasated blood. A careful section of the inflamed part will show this distinctly, and likewise the capillary vessels distended with blood.

When the suppurative or pyopoietic process commences, the gradual loss of colour of the globules, the softening and conversion of the blood into pus, are observed to follow each other in regular succession, both within the capillaries and in the extravasated blood.

Adopting M. Gendrin's elaborate description of the anatomy of the different tissues, when inflamed, we find that inflammation from its very commencement produces a state of infiltration of the tissues: the fluid which is poured forth into the structure of the part appears to be partly vapour, and partly liquid; at least some part of the effused fluid rises in vapour on exposure to the air: at an early stage of the inflammation there is no perceptible coagulum of the fluid. The infiltration differs but little from that of health, excepting in quantity.

But as soon as the inflammation has reached a certain stage of its development, it is very easy to recognise a copious deposition of a substance of the consistence of jelly, interspersed between the fibres of the tissue of the part: at the boundaries of the inflammation, the effused fluid remains liquid and uncoagulated. The fluid poured out into the substance of an inflamed tissue is then no longer in its physiological condition, because it possesses the property of self-coagulation. If the inflammation become very intense, the fluid which is infiltrated, and which coagulates spontaneously, is either reddish or bloody, or it may even be pure blood. This infiltration will appear in all its stages if a transverse section be made into an inflamed part.

Towards the centre of the inflammation the infiltration is composed of pure blood, which sometimes will be found collected in drops. This deposition of blood coagulates during life, and the gelatinous and liquid serosity is distributed in streaks in these clots, or forms around them. The gelatinous infiltration predominates around this central point, and is composed of a reddish substance, partly gelatinous and partly serous, through which blood is dispersed in small streaks. At a greater distance from this centre, the infiltration is more serous and of a yellowish colour, while at the extreme limits of the inflammation, the fluid is entirely serous and colourless: there seems to be a direct relation between the nature of the infiltration

and the degree of vascularity and inflammatory alterations of the tissue of the inflamed part*.

Gendrin likewise describes the appearance of the different tissues, when suppuration begins, in the following terms, (P. 467):—
